Eight acid treated residues (from CF to PCF) were prepared from aliquots of Murchison bulk powder. The procedures were basically similar to previous studies[2,12]. An aliquot of HCl–HF treated residue (CF) which contains sulphides, spinel, chromite and organic polymer was further treated with acetone, hexanes, CS_2, benzene, methanol, 6M NaOH and 30% H_2O_2. This residue, CFO, was separated into a very fine-grained colloidal phase in an H_2O solution (CFOf) and into a coarse-grained residue (CFOc). CFOf was black, its density was 1.25 and it contained the organic polymer, sulphides and spinel. Residue CFOc was grey and contained spinel, chromite and organic polymer. An aliquot of CFOf was treated with boiling NaOH–NaOCl and fuming HNO_3. Two new residues were produced. One (CFOfN) contained organic polymer, chromite and spinel settled out on centrifugation, and the other (CFOfNf) remained dispersed in the solution of HCl-acetone but was recovered by evaporation to dryness. It contained organic polymer, sulphides and spinel. An aliquot of CF was boiled in $HClO_4$ producing a residue, CFP which was white and contained spinel and chromite. To examine the chemical resistivity of trace quantities of ^{13}C-rich carbon present in Murchison, an aliquot of bulk Murchison was dissolved with boiling 70% $HClO_4$ producing a residue, *P* which was white and contained silicates and spinel. An aliquot of this residue *P* was further treated with HCl–HF. This residue PCF contained spinel and silicates. Residue CFS[2] which contained organic polymer, chromite, sulphides and spinel was prepared treating bulk Murchison with HCl–HF solution and with CS_2.

* Acid residues: C, HCl; F, HF; O, H_2O_2; N, HNO_3,; P, $HClO_4$; S, CS_2; f, finer grain fraction; c, coarser grain fraction. Weight percentage of the acid residue and amount of sample used for the analysis are also shown.

† Samples were heated in a quartz vacuum system for 1 h at each temperature in an oxygen atmosphere of ~5 mmHg except the underlined steps where the samples were heated for 4–18 h. *T* in parentheses represents the step where pyrolysis was made in the absence of oxygen. The pyrolyses steps were to analyse separately the terrestrial contamination.

‡ Yields are given in μmol g^{-1} of bulk Murchison.

§ Very low C/H ratios are mainly due to dominance of inorganic hydrogen and very high C/H ratios are due to carbon accumulated at lower temperature steps. Thus each C/H ratio at each *T* step should not be interpreted as a characteristic average C/H ratio of the organic matter decomposed at that temperature.

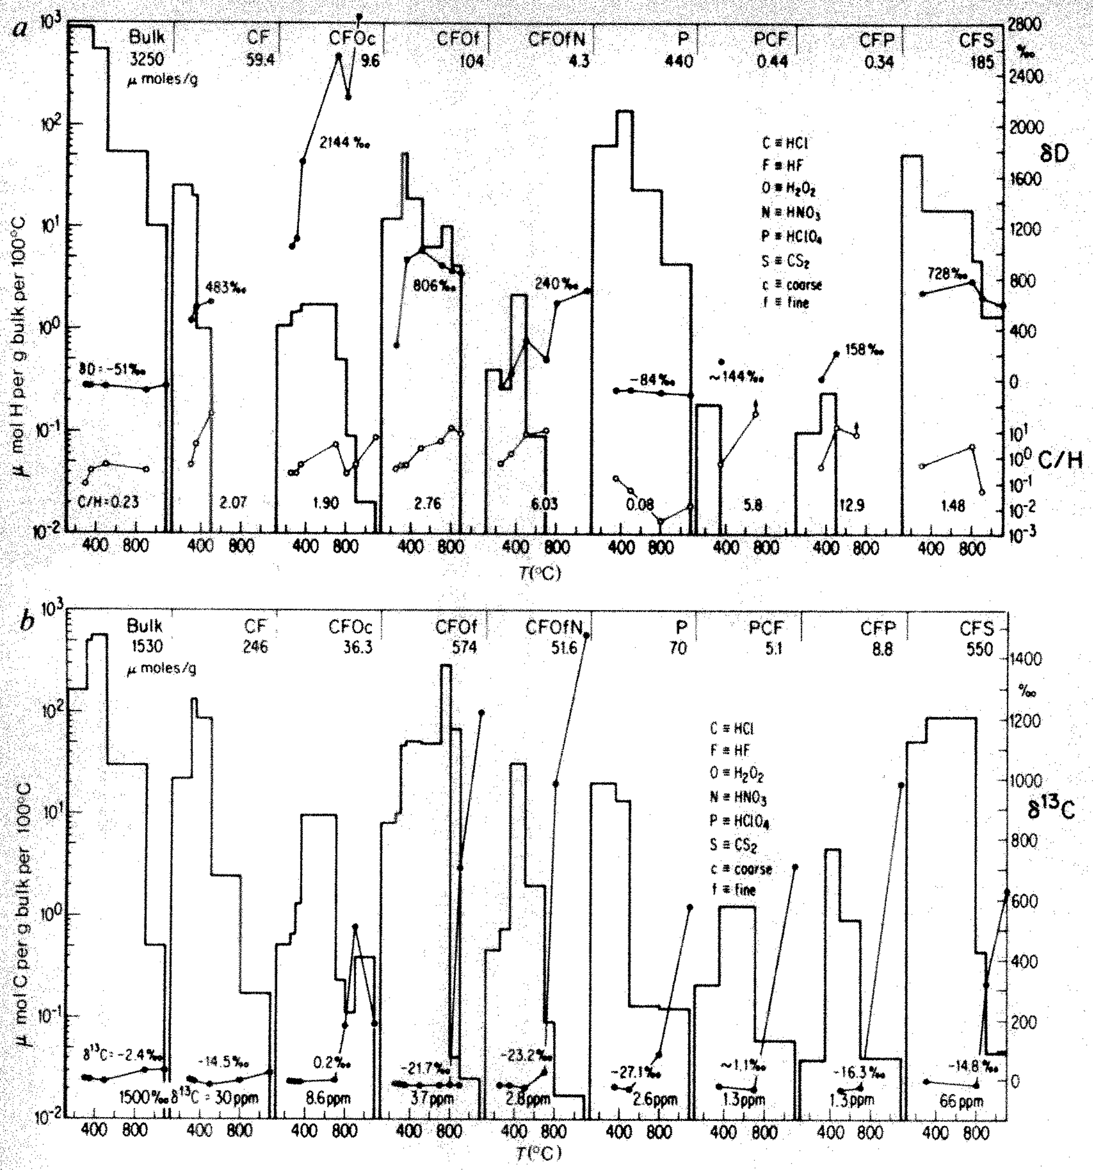

Fig. 1 *a*, A histogram showing the amount of hydrogen released by stepwise oxidations (pyrolysis for lower temperature steps up to 350 °C) of Murchison bulk and acid treated residue samples plotted against the releasing temperature. δD values (●) and C/H ratios (○) of the released gases are also shown. A sample (CFOc) which is composed primarily of spinel and chromite shows the highest δD values of 1,040–2,850‰. Perchloric acid treated samples (P, PCF, CFP) show much lower δD values. Also included are: values for the total H_2 (in μmol g^{-1}), its δD value and the C/H ratio of the total gases. *b*, The carbon released simultaneously with the hydrogen. The concentration of the total carbon, the $\delta^{13}C$ value of the total carbon and the amount of carbon which has $\delta^{13}C$ value of 1,500‰ in units of μg C per g of bulk sample are given.

this means that the CFOc residue, 60% of which is spinel, contains a larger fraction of the preserved interstellar organic matter. The CFOf residue, 70% of which is organic polymer, perhaps contains relatively more of the organic matter formed in the solar nebula at higher temperatures and thus has a lower D/H ratio. Note that HCl–HF residues of many meteorites that we previously examined[2] also contained large amounts of spinel and chromite.

A residue sample (CFOfN) formed by treating CFOf with boiling NaOH–NaOCl solution and fuming HNO_3 shows extremely high $\delta^{13}C$, up to ~1,480‰, and a C/H ratio of 6.0 (Table 1). If it can be assumed that the total carbon in each residue is composed of two carbon sources with nominal $\delta^{13}C$ values of 1,500‰ and −30‰, then residues CF, CFOc, CFOf and CFOfN contain respectively 30, 9, 37 and 3 p.p.m. of the isotopically-heavy carbon component (Fig. 1*b*).

The concentration and $\delta^{15}N$ of nitrogen was also measured for residue samples (Table 1). In the case of the CFOfN sample, most of the nitrogen was released at the 500 °C combustion temperature and the $\delta^{15}N$ value for this N_2 was −170‰, lower than for any other fraction. Our data for total nitrogen (0.21 μmol g^{-1}, $\delta^{15}N = -151‰$) for this sample checks well with the value of Lewis *et al.*[11] (0.16μmol g^{-1}, $\delta^{15}N = -205‰$). There is no correlation between this light nitrogen and isotopically-heavy carbon. Lewis *et al.* came to the same conclusion from their study of acid residues from Allende and Murchison meteorites. They suggested that light nitrogen was produced by neucleosynthesis which is responsible for CCF–xenon. We now suggest an alternative explanation for the −170‰ nitrogen. There seems to be some relationship between the δD and $\delta^{15}N$ in our residues. Thus, the isotopic composition of the nitrogen and the deuterium may be attributable to ion–molecule reactions in the interstellar medium.

Another technique was used to try to isolate the ^{13}C-rich carbon in the residues. The CF residue was boiled in 70% $HClO_4$ and labelled as CFP. The CFP sample contained a concentration of 0.16 μmol g^{-1} of carbon whose $\delta^{13}C$ is 977‰. These are comparable with that observed for residues CFOf and CFOfN (Table 1). However, the CFP residue contained much less total hydrogen and total carbon and almost no nitrogen compared with residues CFOf and CFOfN. Thus perchloric acid is very effective in removing most of organic material but not the very heavy carbon. We, therefore, conclude that the ~1,500‰ $\delta^{13}C$ carbon is not associated with hydrogen and nitrogen. It is quite possible that this small carbon fraction is in a carbide form such as Fe_3C and SiC, or is present as some high-temperature carbon grain such as diamond. Also this result suggests that the low ^{15}N nitrogen and the ^{13}C-rich carbon do not come from the same source.

The perchloric treatment was repeated on an aliquot of Murchison bulk sample. This procedure destroyed 95% of the carbon but the remaining residue (P) contained a heavy carbon component whose $\delta^{13}C$ is ~570‰. This sample, however, contains a large amount of inorganic hydrogen with a characteristic δD value of −80‰, confirming that the hydrogen in this sample is dominantly inorganic. The perchloric acid treatments (P, PCF,

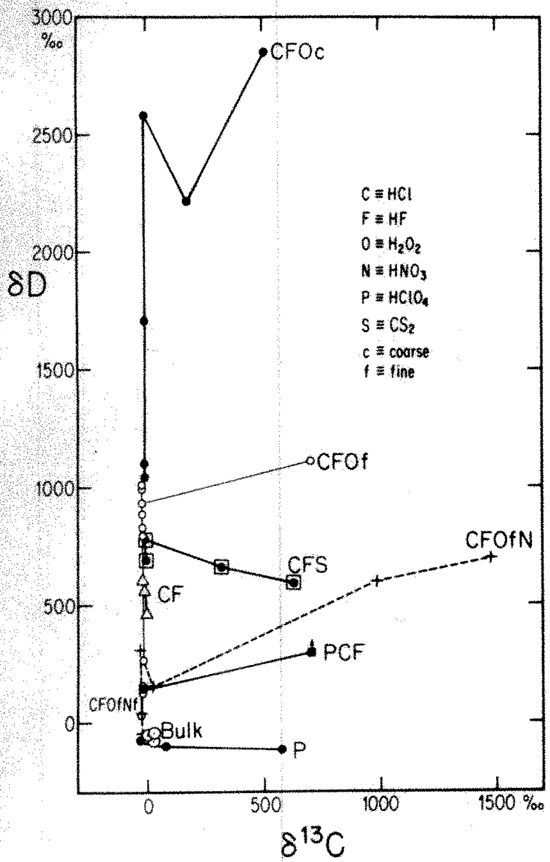

Fig. 2 A plot of the δD against the $\delta^{13}C$ of hydrogen and carbon released by oxidation of Murchison samples. Carbon with high $\delta^{13}C$, up to 1,480‰, was found in the CFOfN residue. This residue consists mostly of carbon with some chromite, spinel and sulphides. There is no clear correlation between the high δD hydrogen and the high $\delta^{13}C$ carbon in the various release patterns and in the various residues, suggesting that they are located in different minerals or different grains. Note that all samples except bulk, CF and CFOfNf have a high $\delta^{13}C$ component which is released on oxidation at high temperatures. The carbon with high $\delta^{13}C$ values compared with the total carbon is preferentially resistant to all chemicals we have used.

CFP) show that the ^{13}C-rich carbon comes from a different source to the deuterium.

We have compared the $\delta^{13}C$ values with δD values of coexisting carbon and hydrogen extracted from various components. This is shown in Fig. 2. The most striking feature of this plot is that the $\delta^{13}C$ values initially recorded up to temperatures of 800 °C are on average about −20‰ whereas the δD values of the hydrogen cover an enormous range of −80 to +2,600‰. On the other hand, at the higher temperature range of extraction of the carbon where $\delta^{13}C$ values range up to 1,500‰, the accompanying hydrogen has relatively smaller up and down variations in δD values. It is difficult to assign a common chemical origin of the meteorite to the D-rich hydrogen and the ^{13}C-rich carbon. The previously mentioned perchloric acid experiments suggested a similar conclusion.

Our experimental procedures will probably add contaminents of low values of δD and $\delta^{13}C$. Consequently, our high $\delta^{13}C$ and δD values are probably minimum values and we hope that procedures will eventually be perfected to allow measurement of the pristine δD and $\delta^{13}C$ values. In the case of hydrogen, the higher the δD values for the extracted hydrogen, the more confident we can become about the proposal that the organic matter and its isotopic composition originated from an interstellar medium due to ion-molecule hydrogen isotopic exchange reactions.

Thus, unusually high $\delta^{13}C$ carbon can be isolated by treating the Murchison meteorite with certain reagents due to the preferential destruction of the ^{12}C-rich components. The fine-grained acid residue (CFOf) contains the highest concentration of the ^{13}C-rich carbon. The ^{13}C-rich component has special chemical properties which will allow its isolation and identification.

The δD of hydrogen does not correlate with the $\delta^{13}C$ of carbon. The coarse-grained acid residue (CFOc) contains hydrogen of the highest D/H ratio while the $\delta^{13}C$ enrichment is relatively modest. The acid residue (CFOfN) which contains the highest ^{13}C-rich component has only modest D enrichment. If the D-rich component is formed by ion-molecule isotope exchange reactions in the interstellar dust clouds, the ^{13}C-rich component is not associated with the deuterium enrichment. This adds credibility to the suggestion by Swart *et al.*[1] regarding the red giant origin of the ^{13}C-rich component in the meteorite.

The fact that the ^{13}C-rich component survived the post accumulation history of Murchison without losing its high ^{13}C value supports our previous assertion[2] that the $\delta^{13}C$ of the major part of the organic carbon in the meteorite is representative of the carbon in the interstellar medium. In addition, the presolar origin of the ^{13}C-rich component in the acid residues of the meteorites agrees with the suggestion that the high D/H ratios observed in the organic matter in the meteorites were due to the preservation of the presolar material. After the D-rich organic matter was incorporated into the meteorite the post-accumulation history for the organic matter should have been sufficiently mild to allow its preservation and its availability for our examination.

We thank Dr I. R. Kaplan for nitrogen analyses, J. Ruth for technical assistance, and Dr E. Olson for a specimen of Murchison meteorite. This research was funded by NASA (NGL-05-002-190) and by NSF (EAR-7816873).

Improved positive-ion composition measurements in the upper troposphere and lower stratosphere and the detection of acetone

G. Hauck & F. Arnold

Max-Planck-Institut für Kernphysik, PO Box 103 980,
D-6900 Heidelberg, FRG

Atmospheric ion composition measurements were recently extended downwards to the lower stratosphere and upper troposphere following development of a new aircraft-borne mass spectrometer technique. Perhaps the most interesting aspect of these measurements is that they can serve as a powerful tool for neutral trace gas detection in passive chemical ionisation mass spectrometry (PACIMS). However, the measurements, in particular those of positive ions, suffer from a poor mass resolution which complicates ion identification and the PACIMS application. Here we report improved positive-ion composition measurements in the lower stratosphere and upper troposphere, using an improved aircraft-borne mass spectrometer with higher mass resolution and sensitivity than hitherto achieved.

The experimental method is essentially similar to one used for our previous measurements[1,2], but with four modifications:

Table 1 Positive ion masses obtained from high-resolution spectra taken in flights F4 and F5 at 11,280 m altitude

Mass	Ion
28 ± 1	HCO^+
	H^+HCN
32 ± 1	H^+CH_3OH
37 ± 1	$H^+(H_2O)_2$
50 ± 1	$H^+CH_3OH \cdot H_2O$
55 ± 1	$H^+(H_2O)_3$
59 ± 1	$H^+(CH_3)_2CO$
64 ± 1	$H^+CH_3COH \cdot H_2O$
	$H^+C_2H_5OH \cdot H_2O$
	$H^+CH_3OCH_3 \cdot H_2O$
	$H^+HCOOH \cdot H_2O$
73 ± 1	$H^+(H_2O)_4$
77 ± 1	$H^+(CH_3)_2CO \cdot H_2O$
88 ± 1	$H^+CH_3OH(H_2O)_2$
114 ± 1	$H^+(CH_3)_2CO(H_2O)_3$
126 ± 1	$H^+(H_2O)_7$

Tentative ion identifications are also given. Instead of H_2O, ions may contain an ammonia molecule although this seems to be less likely.

(1) a larger quadrupole mass spectrometer (rod diameter, 0.8 cm; rod length, 20 cm) providing higher mass resolution and ion transmission; (2) on-axis ion sampling providing a higher sampling efficiency; (3) an ion-dissociation mode allowing for fragment ion studies; (4) a high-frequency glow discharge ion source working at ambient gas pressure and allowing for in-flight calibration and testing.

The modified instrument will be described in detail elsewhere together with laboratory simulation studies; here the ion-dissociation mode will be briefly discussed. After passing through the mass spectrometer inlet hole (diameter, 0.01 cm), located at the tip of a conically-shaped sampling electrode onto which the incoming gas stream is directed, atmospheric ions are electrically extracted from the high-density gas jet forming behind the inlet hole. During extraction they undergo energetic collisions with gas molecules stimulated by the electric field established between the four-pole rods and the sampling cone. As a result, efficient collisional breakup of the ambient cluster ions occurs and thus only fragments, naked- or weakly-clustered 'cores', of the ambient complex cluster ions are ultimately mass analysed and detected.

Typically, the sampling cone is kept at ground potential and the four-pole field axis is several tens of volts, depending on mass resolution. This ion dissociation mode offers two advantages, a larger sentitivity and a better 'core ion' identification. Upper tropospheric positive ions are expected[2] to be heavily hydrated (~6–7 H_2O-ligands) and, therefore, very massive. Fragmentation leads to much smaller ions, which are more successfully transmitted through the four-pole rods (particularly at high mass resolution) and easier to identify.

A few important characteristics of the new instruments are: mass range, 0–1,000 AMU; smallest mass peak width at half peak amplitude $\Delta m = 1$ AMU; sensitivity, ~0.1 ion counts per ion cm^{-3} (depending on mass resolution).

The new instrument has been flown twice (flights F4 and F5) on board a twin jet research aircraft (type FALCON 20) of the DFVLR (Deutsche Forschungs- und Versuchsanstalt für Luft- und Raumfahrt) over the FRG. The flights took place during daytime on 25 November 1983 (F4) and 24 February 1984 (F5). Maximum altitudes of 11,280 m were reached in both flights while the local tropopause heights were 11,900 m (F4) and 9,750–10,036 m (F5). High mass-resolution positive-ion data were obtained only at the float height (11,280 m) where sufficiently long integration times were available and they thus relate to the uppermost part of the troposhere (F4) and the lowermost part of the stratosphere (F5). Lower mass-resolution data obtained in the height region down to 5,300 m will not be discussed here.

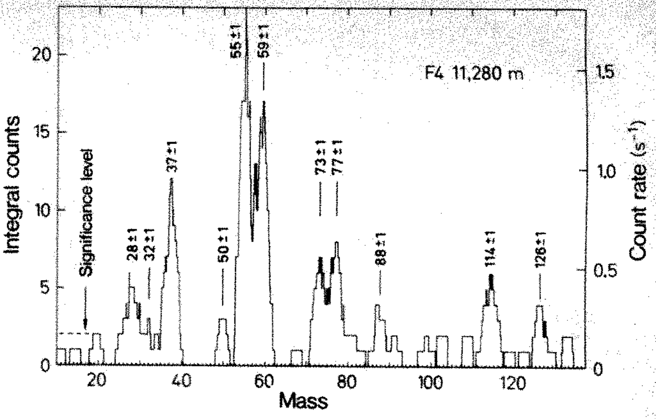

Fig. 1 Positive ion mass spectrum as obtained in flight F4 at 11,280 m altitude. A 2σ significance level is indicated. Total integration time, 640 s.

A typical positive-ion mass spectrum ($\Delta m = 3$ AMU) as measured in F4 at 11,280 m is shown in Fig. 1. As confirmed by the larger mass range, but lower mass-resolution studies, made in F4 at the same height, all major positive ion peaks fall into the mass range shown by the spectrum. Among these, 55 ± 1 and 59 ± 1 are most prominent peaks followed by 37 ± 1, 73 ± 1, and 77 ± 1. A compilation is given in Table 1 along with tentative ion identification. The ions 37 ± 1, 55 ± 1, and 73 ± 1 may readily be identified as proton hydrates ($H^+(H_2O)_n$; $n = 2, 3, 4$) which were previously found in the stratosphere[3–5] and which are expected[6,7] to form quickly at the tropopause from primary positive ions produced by galactic cosmic-ray ionization. In view of the mass uncertainty of ±1 AMU, which is mainly due to poor ion counting statistics, it is also possible that the core ion is NH_4^+ instead of H_2O.

The size distribution of the observed $H_3O^+(H_2O)_n$ or $NH_4^+(H_2O)_n$ clusters peaks at n equal to 2 which is quite different from the distribution of ambient $H_3O^+(H_2O)_n$ ions[2] which should peak at around n equal to 6 and 7. Thus, there is clear evidence for massive electric field-induced dissociation which greatly facilitates the identification of other observed ions.

To improve mass identification of the most prominent peaks observed in F4 (55 ± 1 and 59 ± 1), a much higher mass resolution ($\Delta m = 1$ AMU) was used in F5. However, most of the mass range had to be sacrificed for the high-resolution study to gain integration time for the mass range of interest (50–71 AMU), and thereby to offset the lower sensitivity associated with higher resolution. The portion of the spectrum scanned in the high-resolution mode ($\Delta m = 1$ AMU) of F5 is shown in Fig. 2 along with a lower resolution ($\Delta m = 3$ AMU) spectrum of the same flight. Surprisingly, the spectrum is quite different from that shown in Fig. 1 with 55 ± 1 being virtually absent. However, peak 59 is present, and its mass can be unambiguously identified. The large mass range, low-resolution studies made in F5 reveal that peak 59 is the most prominent one in the entire mass range, and that only minor peaks of other ions are present.

To identify ion 59, the following arguments should be considered: (1) the ion seems to be an unhydrated 'core ion' as no fragment having a mass of 41 is observed; (2) the hydrate of 59 seems to have a stability which is similar to the stability of $H_3O^+(H_2O)_3$ or $NH_4^+(H_2O)_3$ as suggested by the similarity of the ratios 77 ± 1/59 and 73 ± 1/55 ± 1; (3) ion 59 is probably a fragment of ions formed by the reaction of $H_3O^+(H_2O)_n$ with an atmospheric trace gas which possesses a proton affinity sufficiently larger than that of H_2O (165.3 kcal mol^{-1})[8].

If correct, the first argument immediately suggests protonated acetone $H^+(CH_3)_2CO$ which is rather stable due to the large proton affinity of acetone (193.8 kcal mol^{-1})[8]. Unfortunately, the bond energy of $H^+(CH_3)_2CO \cdot H_2O$ is not known and, therefore, the second argument cannot be checked. However, bond

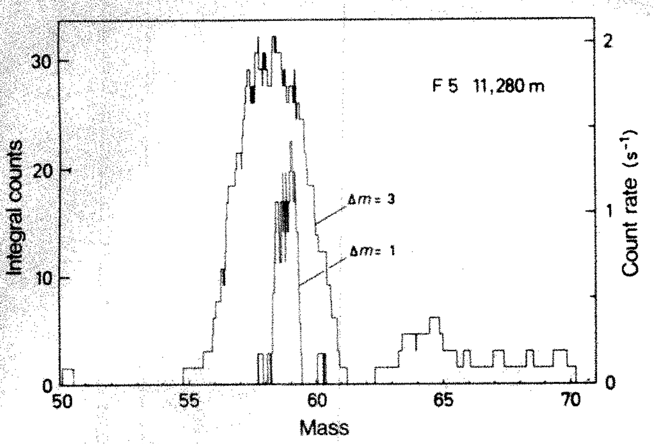

Fig. 2 Portions of positive ion mass spectra with different peak widths at half-peak amplitude, Δm, of 3 and 1 AMU obtained during flight F5 and 11,280 m altitude. Total integration times, 100 and 410 s.

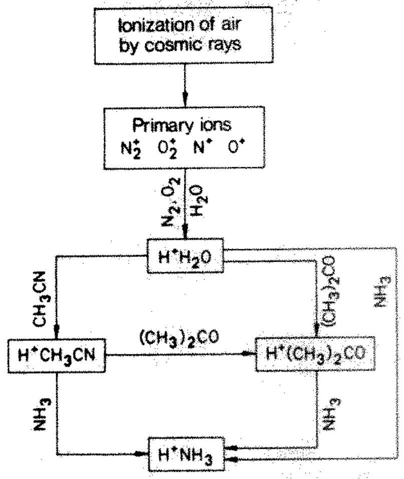

Fig. 3 Simplified reaction scheme for major positive core ions in the upper troposphere and lower stratosphere.

energies for hydrates of large core ions similar to $CH_3CH_2CO^+$ have been measured in the laboratory[8] and were found to be around 17 kcal mol^{-1} which is, in fact, the same bond energy as $H_3O^+(H_2O)_3$ (ref. 8).

High-pressure flow reactor studies, recently carried out at our laboratory, have revealed that at an ambient pressure of 200 mbar (corresponding to an altitude of around 11.000 m), $H^+(CH_3)_2CO(H_2O)_n$ clusters are severely dissociated with $H^+(CH_3)_2CO$ being the most prominent fragment ion. It was also found that the fragmentation behaviour was similar to that of $NH_4^+(H_2O)_n$ clusters, which are less strongly bonded than $H_3^+O(H_2O)_n$ clusters (the bond energy for $NH_4^+H_2O$ is only 17.2 kcal mol^{-1})[8].

Thus, protonated acetone seems the most likely identification of peak 59. The strongest argument, however, comes from CIMS measurements[9], also made on flight F5, which reveal the presence of substantial amounts of acetone vapour at 11,280 m (acetone volume mixing ratio, 100 parts per 10^{12}, p.p.t.). Considering the latter acetone abundance one would expect acetone containing clusters to be the most dominant ions, which was in fact the case in F5. From a comparison of the CIMS-and the present ambient ion measurements we can conclude that the $H^+(CH_3)_2CO$ ions are not due to acetone contamination[9].

If peak 59 was protonated acetone, it seems likely that observed ion families, other than $H_3O^+(H_2O)_n$, are also represented primarily by their naked cores ($n = 0$). This is to be expected since such ions, including NH_4^+ usually have much smaller hydration energies compared with H_3O^+. Thus 55 ± 1 is probably $H_3O^+(H_2O)_2$ and not $NH_4^+(H_2O)_2$.

Of the other observed ions (Fig. 1), 33 ± 1 may be identified as protonated methanol or formaldehyde with 50 ± 1 possibly being its hydrate. The ion 28 ± 1 may be attributed to HCO^+ which could be a fragment of protonated acetone[9]. Tentative identifications for the remaining minor peaks are included in Table 1 and will not be further discussed here. Positive ions with masses 29, 31 and 33 are also present in the CIMS spectra of F5 (ref. 9).

From the above, it seems that much more acetone vapour must have been present at 11,300 m in F5 compared with F4. Considering a typical rate coefficient of 2×10^{-9} cm^3 s^{-1} for reaction of acetone with $H_3O^+(H_2O)_n$ clusters, and an ion–ion recombination lifetime of 130 s acetone abundances of about 1 p.p.t.v. (F4) and ≥ 20 p.p.t.v. (F5) have been estimated[1,2]. However, if the ions 37 ± 1, 55 ± 1 and 73 ± 1 (F4) were not $H_3O^+(H_2O)_n$, but $NH_4^+(H_2O)_n$ clusters, the above steady-state treatment would not apply.

Acetone vapour measurements at ground level (typically 500 p.p.t.v.) have recently been reported by Penkett[10] using a GC–MS technique. Destruction of acetone (S. Penkett, personal communication) by OH-reaction (lifetime ~1,300 h) and photolysis (lifetime of ~500 h), although being sufficiently slow, allow efficient vertical mixing of acetone. However, heterogeneous removal may also operate in the troposphere and, unfortunately, very little is known about this potential acetone sink. Sources of acetone seem to be photo-oxidation of C_3H_8 or higher aliphatic hydrocarbons[10,11], preferably through OH-reaction.

Finally, we consider an implication of the present data for lower stratospheric ammonia abundances. If peak 59 is, in fact, protonated acetone, the ammonia abundances at 11,280 m must have been very low for both F4 and F5. This is because $H^+(CH_3)_2CO(H_2O)_n$ clusters should react efficiently with ammonia. Using a steady-state treatment analogous to the one discussed above, the upper limits to the ammonia abundance at 11,280 m are estimated to be ~1 p.p.t.v. (F4) and ~0.05 p.p.t.v. (F5).

From the preceding discussion, a simplified picture of the ambient positive-ion chemistry emerges (Fig. 3). Primary ions formed by cosmic ray ionization of air are quickly converted to H^+H_2O 'core' ions which are strongly hydrated (~6–7 H_2O ligands). Reactions of H^+H_2O 'cores' with the large proton-affinity trace gases acetonitrile and acetone which are almost equal around the tropopause[9], lead to corresponding H^+CH_3CN and $H^+(CH_3)_2CO$ 'cores'. Incorporation of these molecules into the clusters may also lead to mixed clusters. At lower heights, ammonia vapour[12,13] becomes abundant enough to convert most of the $H^+(CH_3)_2CO$ 'cores' to H^+NH_3. Above the tropopause, acetone seems to decrease more rapidly than acetonitrile and ultimately has such a low abundance in the middle stratosphere that H^+CH_3CN conversion becomes inefficient, as suggested by the observed[4] dominance of H^+CH_3CN cores around 25-km altitude. At even higher altitudes (upper stratosphere), the acetonitrile abundance becomes low enough to prevent efficient transformation of H^+H_2O cores. It is not known at which heights the transitions from dominant H^+NH_3 to $H^+(CH_3)_2CO$ and from $H^+(CH_3)_2CO$ to H^+CH_3CN cores occur.

Future ion composition measurements should be extended downwards in altitude to search for clusters containing H^+NH_3 and other cores with large proton-affinity molecules. Thus *in situ* ion composition measurements may also become a powerful tool for tropospheric trace-gas detection.

We thank E. E. Ferguson, P. Crutzen, D. Ehhalt and D. Griffith for helpful discussions, the technical staff of the MPI-K, particularly K. Oberfrank and the Flugbereitschaft of the DFVLR for assistance. This project was funded by the Bundesministerium für Forschung und Technologie through GSF.

Microdomains observed at the ferroelectric/paraelectric phase transition of barium titanate

L. A. Bursill & Peng Ju Lin

School of Physics, University of Melbourne, Parkville, 3052,
Victoria, Australia

The physical properties of barium titanate have been thoroughly studied because of fundamental interest in its singular ferroelectric properties and the wide variety of applications[1]. Inelastic neutron and X-ray diffraction studies suggest that the atomic mechanism for the phase transition from the paraelectric (cubic) to ferroelectric (tetragonal) phases lies somewhere between the extremes of 'displacive' and 'order–disorder' models[1,2]. Analysis of the 'central-peak' phenomena[2,3] has led to microdomain models, while molecular dynamic computer studies for ferrodistortive and antiferrodistortive phase transitions predict travelling clusters of locally-ordered regions, with slowing-down and increasing cluster size close to the critical temperature[4]. Direct evidence for the occurrence of microdomains has been obtained by *in situ* electron microscopy of the transition.

Slices (200 μm) of a crystal of $BaTiO_3$ were mechanically thinned parallel to a pseudocubic face. These were chemically thinned using orthophosphoric acid and sandwiched between two 75-mesh grids. Specimens were observed in a Gatan double-tilting heating–cooling goniometer ($-180 < T < 150$ °C) in a JEOL-100CX electron microscope. Images were recorded as a function of temperature using standard photographic techniques as well as a television camera with videotape recorder.

The room-temperature observations closely followed the results of Tanaka and Honjo[5]. Thus 90° domains of a–c and a–a type occurred frequently (see ref. 6, Fig. 2). On heating above 120–130 °C, a faint contrast appeared between existing domain walls (Fig. 1). Approximately equal areas of light and dark contrast occurred, with periodicity ~425 ± 25 Å. Dots of contrast and wavy lines occurred with ill-defined orientation and connectivity. This 'microdomain' contrast could be enhanced (Fig. 1) by tilting off the [001] zone axis by a few degrees and using the *hh*0 systematic row diffraction condition (L.A.B. and P.J.L., in preparation). For a wedge-shaped crystal (Fig. 2) the microdomain periodicity varied systematically with crystal thickness, ranging from ~250 Å in the thinnest areas, to ~1,200 Å for a crystal thickness of ~1,000 Å. Displacing or focusing the electron beam did not change the gross features of the pattern and no sideways movements of the microdomains could be induced. This behaviour is quite distinct from that of a–c or a–a ferroelectric domain walls, which could be induced to move sideways quite readily by moving or focusing the electron beam. Closer examination of videotapes showed fluctuations within microdomain contrasts (see arrowed positions in Fig. 3). Thus, for specimens thermally equilibrated at temperatures in the range 130–140 °C, small patches of darker contrast (~40–60 Å diameter) could be seen to transfer across the domain walls between adjacent dark contrast spots or stripes. The overall periodicity and texture of the microdomains were maintained, but they clearly possessed a dynamic character on a finer (20–40 Å) scale. Such movements, detectable at 25 frames s^{-1}, probably contribute to the diffuse appearance of the microdomain wall contrast. Such fluctuations were not simply due to small tilts during observation, as judged from the stability of bend extinction contours.

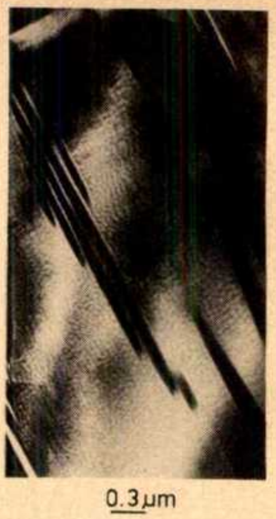

Fig. 1 Microdomain contrast within ferroelectric domains in a $BaTiO_3$ crystal observed at 120–130 °C (pseudocubic projection axis). Note equal areas of light and dark contrast with periodicity ~425 Å.

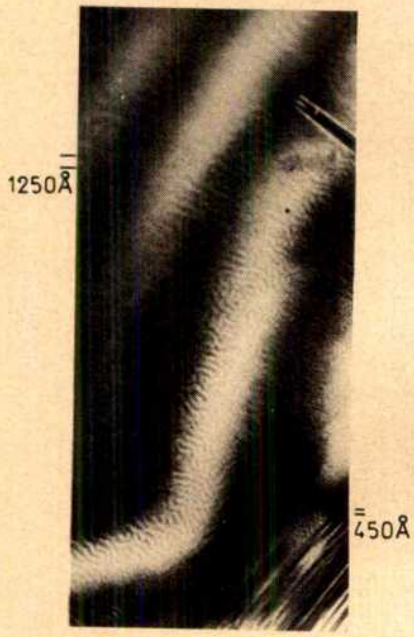

Fig. 2 Thickness dependence of microdomain periodicity in wedge-shaped crystal of $BaTiO_3$ (pseudocubic projection).

Attempts were made to establish systematic relationships between microdomain size and/or fluctuation frequency and temperature. These were not conclusive. On cooling the specimens from 140 °C to room temperature, the microdomains sometimes disappeared at ~100–120 °C but sometimes remained stable to ~60–80 °C. They did not occur at room temperature. The stability of microdomains on cooling appeared to be related to the topology of the specimen, in particular to elastic bending, and to the cooling rate. There was no systematic variation of domain size on cooling, and the microdomains probably disappear suddenly rather than gradually. The onset temperature was more sharply defined, being 127 °C for three different experiments, indicating reproducible behaviour. In other experiments the onset temperature varied between 130 and 150 °C. Thus exceptionally flat and extensive wedge-shaped thin edges, which were initially free of a–c or a–a domain walls, were strongly

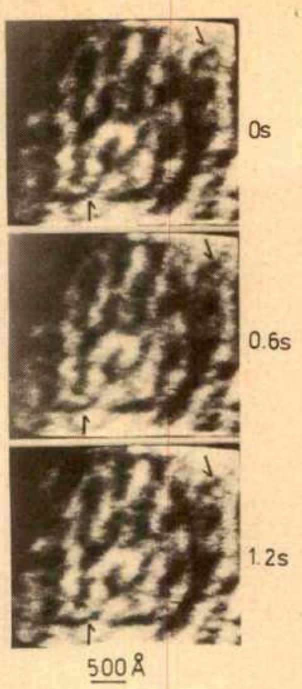

Fig. 3 Time sequence from videotape recording showing fluctuations in microdomains at 140 °C (25 frames per s). Note transfer of small (50-Å diameter) areas of darker contrast between adjacent microdomains, whereas the overall domain periodicity and topology is essentially maintained.

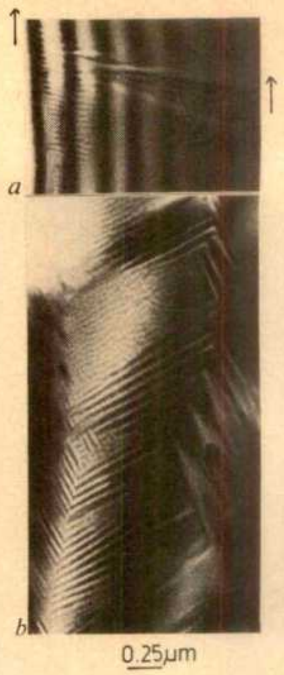

Fig. 4 *a*, Divergence of a–c domain wall at 140 °C, creating a slab containing microdomains bounded by inclined boundaries. Note one-dimensional nature of microdomains, lying parallel to existing a–c wall. *b*, Elements of two-dimensional short-range-ording of microdomains, apparently imposed by topology of coexisting a–c ferroelectric domain walls.

resistant to microdomain nucleation, even up to the maximum available temperature (150 °C).

Microdomain nucleation was clearly demonstrated for such a wedge-shaped crystal which contained only a single a–c domain wall. This wall remained quite stable until 140 °C and then suddenly diverged to create a slab containing microdomains bounded on either side by fault fringe contrast (Fig. 4*a*). Slight changes in the incident beam illumination angle were then enough to cause this slab to expand or contract, following movement of the incident beam. The microdomain texture often showed topology apparently determined by that of existing a–c or a–a domains. Thus for Fig. 4*a* the microdomains form essentially a one-dimensional array, parallel to the existing (011) wall, whereas in Fig. 4*b* some elements of two-dimensional short-range order appear to be imposed by orthogonal (011) and $(01\bar{1})$ a–c domain walls. The fine scale of the latter sometimes appears as a precursor to microdomain formation. In other areas (see Figs 1 and 2), the microdomains do not show preferred orientations.

Dark-field observations of the microdomains will be discussed elsewhere (unpublished work), as will other results for domain wall kinetics, recorded for $-180\,°\mathrm{C} \leq T \leq 150\,°\mathrm{C}$. These also concern the tetragonal/orthorhombic (5 °C) and orthorhombic/trigonal phase transitions. Distinctive behaviour often occurred at thin edges and cracks.

The observed mechanism of microdomain formation, by a–c or a–a wall divergence, and the fine-scale fluctuations involving transfer of one-ferroelastic orientation between adjacent microdomains should add more reality to molecular dynamical[4] and other theoretical approaches to the understanding of structural phase transitions[2].

The structure of the microdomains and hence contrast mechanisms have not been determined. Five important new observations need to be explained: (1) apparently equal volumes of bright and dark contrasts appeared in every case recorded; (2) the microdomains did not readily interact with the electron-beam, whereas a–c and a–a domain walls in the tetragonal phase move readily on focusing or translating the incident beam; (3) the microdomain contrast is relatively very weak compared with normal 90° domain wall contrast; (4) the microdomain walls are relatively diffuse and subject to fine-scale fluctuations; and (5) microdomains may coexist with normal a–c or a–a domain walls, often showing topology apparently related to the latter.

The following tentative interpretation of the structural mechanism for the ferroelectric/paraelectric phase transition is based on these observations. We propose that the bright and dark microdomains contain a structure intermediate between that of the well-known[1] tetragonal and cubic forms of $\mathrm{BaTiO_3}$. This transition structure could simply be a tetragonal distortion of the cubic phase. This would allow domain formation and give reasonable changes in background contrast across the microdomain walls (L.A.B. and P.J.L., in preparation). It should also be paraelectric, so that there is no electrical interaction between the incident beam and the microdomain walls. The transitional phase could also be ferroelastic, with noncentrosymmetric displacements of the oxygen atoms with respect to the cubic phase, but retaining zero electric dipole moment. Such a structural mechanism is respresented in Fig. 5. Clearly, the tetragonal distortion may take different orientations with respect to the cubic (or tetragonal) axes, but to minimize elastic strain overall, equal volumes of symmetrically equivalent domains should occur. The coexistence of a–c or a–a ferroelectric domains in the tetragonal phase, together with microdomains of the transitional phase (Fig. 4*b*), occurs over a range of temperatures, and a strong influence of the former on the topology of the latter is to be expected, as the structural difference involves small atomic displacements within virtually identical tetragonal unit cells (Fig. 5).

Our observations (Fig. 3) give some insights into the question of microdomain dynamics. The observation of a sharp onset temperature for microdomain formation (Fig. 3), rather than a gradual coarsening with increasing temperature, suggests that some modification of the models used for molecular dynamical calculations is required.

The present work has obvious limitations. First, the restriction to $T \leq 150\,°\mathrm{C}$ meant that it was not possible to study the stability of microdomains within the cubic phase. The molecular dynamic computations may then be more appropriate, with behaviour

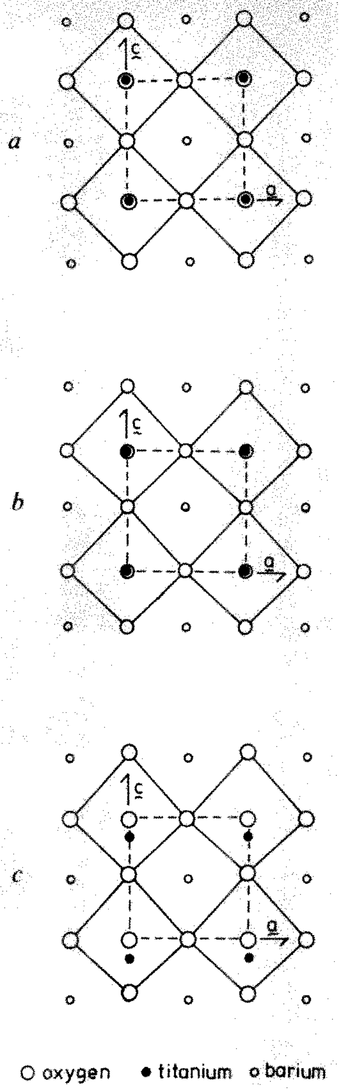

Fig. 5 Structural relationships between cubic (*a*), transitional (*b*) and tetragonal (*c*) phases of $BaTiO_3$.

quite different from that within the tetragonal phase. Second, the observed thickness dependence of microdomain periodicity (Fig. 2) indicates that at least some of the observed behaviour may not be characteristic of the bulk. Further studies using higher voltage instruments are required.

Clearly, transmission electron microscopy may be used to study some aspects of critical fluctuation phenomena associated with structural phase transitions. The present *in situ* studies have provided insights into the ferroelectric/paraelectric transition in barium titanate and the techniques used should have much wider applicability, even given that there may be some limitations, especially with regard to the applicability of the results for bulk crystals. However, many future device applications, and hence fundamental interests, are likely to involve thin films.

Invariant and changing transitional field configurations in a sequence of geomagnetic reversals

Jean-Pierre Valet & Carlo Laj

Centre des Faibles Radioactivités, Domaine du CNRS,
Avenue de la Terrasse, 91190, Gif-sur-Yvette, France

In the past few years, the increasing number of detailed records of geomagnetic transitions has provided new and important information about the behaviour of the Earth's magnetic field during a reversal. Surprisingly, however, no attempt has been made to obtain information about the evolution of the transitional field characteristics over a long period of time. We report here the results of a palaeomagnetic study of four different geomagnetic reversals, three of which are successive, recorded at different stratigraphical levels of two Upper Tortonian marine clay sections in western Crete (Greece). This sequence represents ~1.5 Myr of geomagnetic field history. The results obtained suggest that the process of reversal from either starting polarity may remain invariant for a long period of time, then change rather abruptly between successive reversals.

The two sections investigated are situated 5 km apart in the Kastelli basin in western Crete, near the villages of Potamida and Skouloudhiana. A careful correlation between these two sections, among others, has been established by a previous extensive bio- and magnetostratigraphical study of late Miocene sediments in Crete[1]. The location of the two sections is shown schematically in Fig. 1, together with the corresponding correlated polarity sequences. Correlation with the geomagnetic time scale shows that the two sections combined cover the time interval between 7.4 and 5.3 Myr, and that the four reversals studied here are spread over a time interval of ~1.5 Myr (ref. 1).

Some of the results obtained from these two sections have already been reported[2–4]. We add here new results for the normal–reversed (N–R) KS 05 transition. Moreover, extensive resampling has allowed us to obtain further transitional palaeomagnetic directions, so that all the palaeomagnetic records may be classified as category A, as defined by Fuller *et al.*[5].

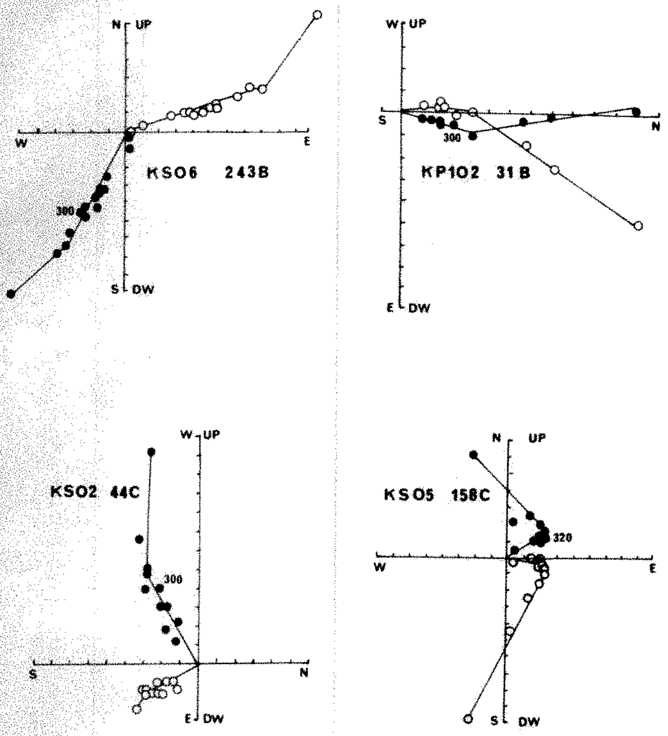

Fig. 2 Typical thermal demagnetization diagrams of samples from KS 02, 05, 06 and KP1 02 transition zones. ●, Declination data; ○, inclination data.

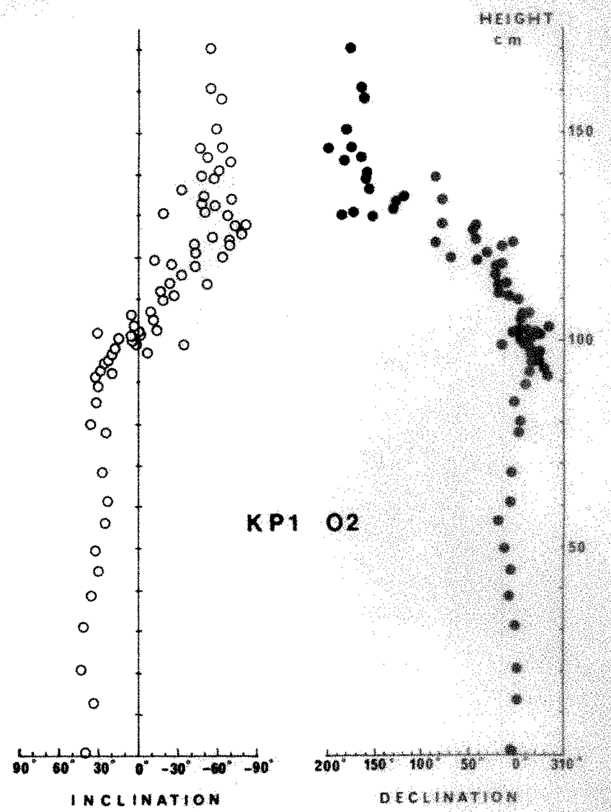

Fig. 3 Detailed declination/inclination record relative to the (N–R) KP1 02 transition in the Potamida 1 section.

The sampling was done using standard palaeomagnetic techniques, with either water or compressed air as a coolant. Care was taken to determine the exact relative stratigraphical position of the cores in each transitional zone. Repetitive measurements yielded identical results within 0.5 cm. The exact stratigraphical height of the different samples obtained from each core was calculated using a computer program which took into account the usual orientation parameters of the core, its stratigraphical position and even the width of the diamond saw used to cut the cores. The magnetic properties of the clays have been carefully investigated to check that there are no changes in the magnetic or sedimentary mineralogy over the different transitional zones. Isothermal remanent magnetization (IRM) measurements show that, in all cases, magnetite is the main magnetic mineral, with a very small amount of a mineral of higher coercivity, presumably haematite, also generally present.

The anisotropy of the magnetic susceptibility has also been measured at different horizons of the two sections. In both cases, the magnetic fabric is described by an oblate ellipsoid with a very moderate (1.05) degree of anisotropy. In Skouloudhiana, the mean $K_{\min}$ axis is perfectly perpendicular to the bedding plane (inclination $I = 88.5°$) while the $K_{\max}$ axes of the individual samples show no preferential orientation in this plane. In Potamida 1, the well grouped $K_{\min}$ axes dip slightly in a northeasterly direction and there is a preferential north–south trend of the $K_{\max}$ axes. The magnetic lineation $(3(K_{\max} - K_{\text{int}})/(K_{\max} + K_{\text{int}} + K_{\min}))$ is, however, very small (0.014), so that in both sections the results indicate a planar undisturbed sedimentary fabric.

Stepwise thermal demagnetization of all samples has been used and the magnetization was measured with either a Digico spinner magnetometer or a three-axis LETI cryogenic magnetometer. For the most weakly magnetized samples, and in particular for all the samples of the KS 05 transition, the double precision procedure of Vandenberg[6], involving four independent measurements for each sample, was used with the cryogenic magnetometer. In spite of this procedure, some of the demagnetization diagrams can hardly be judged to be linearly decreasing. These diagrams which represent ~30% of the total in KS 05, were not taken into account in the final results. No such problems were encountered for the other transitions.

Typical demagnetization diagrams of samples from four different reversals are shown in Fig. 2; these are plotted relative to transitional samples so that they correspond to the lowest natural remanent magnetization (NRM) and most delicate part of each transition. It can be seen that, apart from a secondary, probably viscous, component removed at low temperature (≤ 250 °C), only a single stable component of magnetization is present.

The magnetic susceptibility of samples from each transition was monitored during progressive demagnetization using a susceptibility bridge. No changes of more than a factor of three were found between room temperature and 500 °C, indicating that no major mineralogical transformations had affected the magnetic materials.

Palaeomagnetic directions were obtained by hand fitting a straight line through the last points of the demagnetization plots. As an example, the complete declination–inclination record for transition KP1 02 is shown in Fig. 3.

In all the sediments, the mean inclination of the samples situated well outside the transition zones is about 8–10° shallower than that expected at the site latitude on the basis of a geocentric axial dipole. This is a general property, not only of Potamida and Skouloudhiana[1,2], but also of all sediments of the same nature throughout the Hellenic sedimentary arc[7]. A correction of this error using a formula such as $\tan I' = f \tan I$ (ref. 8) does not, however, significantly change estimates of the virtual geomagnetic pole (VGP) paths[2] and we have therefore worked with uncorrected measurements.

From the directions obtained from the demagnetization diagrams, the successive VGP positions have been calculated for the five transitions. The results are shown in Fig. 4 together

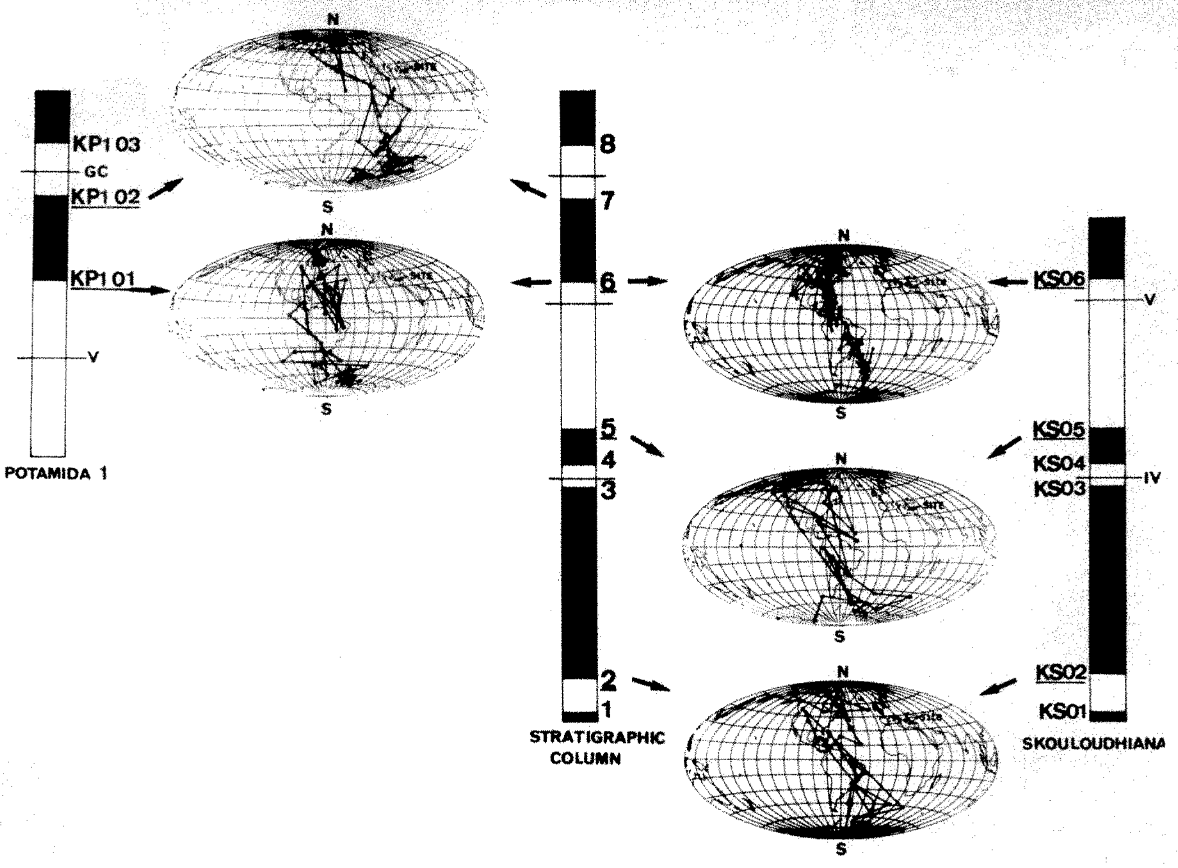

Fig. 4 VGP paths of the five polarity transitions (north VGPs for the R–N and south VGPs for the N–R transitions). The composite total stratigraphical column in the centre gives the stratigraphical position of the transitions. The VGP paths of the lower three transitions are identical within noise limits, while the upper one differs by ~60° long.

with the stratigraphical position of the reversals. To compare directly the VGP paths corresponding to transitions of opposite sense, we have plotted in Fig. 4 the north VGPs associated with R–N transitions and the south VGPs associated with the N–R transitions, as suggested by Hoffman[9].

It can be seen from Fig. 4 that, within noise limits, the VGP paths associated with the transitions KS 06 and KP1 01, which represent the record of the same transition in the two sections, are identical. This, of course, is a condition that must be fulfilled if transitional VGP paths from the two sections are to be compared; the fact that it is suggests that differences in the VGP paths of other transitions are probably a result of changes in the reversal mechanism and not of distortion in the sampled sections.

The main result (Fig. 4) is that the north-VGP paths associated with the two (R–N) transitions, and the south-VGP path for the (N–R) transition in Skouloudhiana, are identical. In spite of significant scatter, which is a consequence of the low magnetization of the sediments for the two lower transition zones, even an east to west migration of the intermediate VGPs can be recognized in these plots as already noted by Hoffman[9]. The directional field variation at the site during this (N–R) transition is thus identical to that associated with the R–Ns except for a change in sign. (This situation is exactly opposite to a standing field situation which requires identical transitional field along with sign, but is consistent with a flooding model.)

On the other hand, the south-VGP path relative to the upper (N–R) transition in Potamida 1 is significantly different, being about 60° of longitude away from the other paths.

The marine sediments used in this study have an average sedimentation rate of $\sim$4–5 cm kyr^{-1} (ref. 1). Therefore, they may not record changing field directions as faithfully as rapidly deposited lake sediments or, indeed, volcanic rocks. These sediments have, however, proved to be a faithful record of the direction of the steady magnetic field to within a few degrees[1,7]. It is, thus, very difficult to imagine that poor remanence acquisition processes for a rapidly changing field, such as long integration times for the locking-in of the remanence, would modify the general features of the reversal records. In particular, we cannot think of any process which would result in antipodal reversal paths for the different transition senses. This feature, in contrast, can be taken as proof of the reliability of the palaeomagnetic records.

These results, therefore, suggest that the process of reversal from either starting polarity remained unchanged during the time interval of 1.2–1.3 Myr, corresponding to the first three reversals[1]. A change then occurred in the period between the two upper reversals. This change must have occurred rather abruptly, because these two reversals are separated by <250,000 yr (ref. 1).

Similarities, or even coincidence, of VGP paths of different transitions, recorded in different, but geographically close, sites, have already been reported[10–12]. Hoffman has even suggested, on the basis of four Cenozoic transitions in the western US that because of particular conditions in the core, only a very limited number of possible reversal configurations might be liable to occur with finite probability at any epoch, so that only particular ones will be frequently observed in time[13]. The results reported here are, however, the first to suggest that the mechanism of reversal is invariant over a long period of time, confirming previously reported results[3].

Moreover, these results from the upper Tortonian epoch cannot be reconciled with the standing field model. It is thus interesting that a set of two successive palaeomagnetic reversals obtained by Bogue and Coe from slightly younger (5.6–4.5 Myr) lava flows in Kauai yield, in contrast, very similar paths[14]. These authors have noted that unless the standing field or the flooding process can, at least occasionally, change from reversal to reversal, neither model can explain all the available transition data. The present results, together with those from Kauai, suggest that such changes in the reversal process might occur not only from reversal to reversal but also between different epochs, so that a particular process might be more effective during a particular period of time.

In this respect, the results from the (R–N) KP1-03 transition would be quite interesting. Indeed its age is 5.6 Myr (ref. 1), so that it could eventually provide a link between the results from Crete and those from Kauai. Unfortunately the sediments in the KP1 03 transition zone are weakly magnetized and furthermore a ferrugineous level is present in this zone[1]. Thus, such measurements would be quite difficult to achieve.

We thank Cor Langereis for invaluable field assistance, H. Zijderveld for many helpful discussions, and K. Hoffman for detailed comments and suggestions. The Director General of the Institute of Geological and Mining Research (IGME) in Athens provided the necessary permits. C. Kissel, S. Sen and M. Villeger helped with the sampling. This work was supported by the French CNRS ATP Géologie et Géophysique des Océans.

Density of the ocean crust

R. L. Carlson & G. S. Raskin

Department of Geophysics and Geodynamics Research Program,
Texas A&M University, College Station, Texas 77843, USA

The density structure and average density of the oceanic crust have implications for various geological and geophysical problems, including interpretations of gravity data, the variation of lithospheric bouyancy in relation to age, and role and fate of the crust in subduction. But no systematic evaluation of oceanic crustal density has been made and estimates range from 2.85 to 3.0 Mg m^{-3} (refs 1–3). We have made an evaluation based on seismic refraction data in combination with drilling results, laboratory studies of seismic properties of oceanic and ophiolitic rocks, and ophiolite lithostratigraphy. Our preferred value for the mean density of the oceanic crust is 2.89±0.04 Mg m^{-3}.

Seismic refraction data provide the most important constraints on the structure and composition of the oceanic crust. (Seismic models and their interpretation in terms of composition are given in refs 4, 5.) Over the past decade or so, simple three-layer velocity-structure models have given way to more detailed multilayer models, and synthetic seismogram modelling has led to more sophisticated 'gradient' models.

Synthetic seismogram models indicate that the upper 2 km of igneous basement (layer 2) is characterized by strong vertical velocity gradients, with P-wave velocities ranging from <4 km s^{-1} at the top to >6 km s^{-1} at the bottom of the interval. Layer 2 may, nevertheless, be subdivided into layers (2a, 2b, 2c), though these regions may not be homogeneous or separated by distinct discontinuities[5,6]. The rapid increase of velocity with depth in layer 2 may be attributed to several factors: (1) velocities in the upper 200–400 m of the section are significantly reduced by large-scale porosity (produced, for example, by collapsed pillows,.and lava tubes)[7–9]; (2) there is a systematic decrease of grain-boundary porosity with depth[10–12]; and (3) metamorphic grade increases with depth; greenschist facies mineral assemblages (chlorite, epidote, actinolite, albite) are associated with layer 2c in hole 504B (ref. 9). In contrast to layer 2, velocity gradients in oceanic layer 3 are low (0.0–0.1 S^{-1}). The velocity at the top of the unit is typically 6.7–6.8 km s^{-1}, but the internal structure of layer 3 is apparently variable. In some cases, the gentle gradient extends to the Moho; in others the layer may be subdivided into two (or more) units[4,5,13]. The transition from crustal to mantle velocities generally occurs over an interval of ~1 km.

The oceanic crust can be approximated by a layered sequence, having an average density given by

$$\rho_{\mathrm{avg}} = \frac{1}{T}\sum_{i=1}^{n} \rho_i t_i;\ T = \textstyle\sum_{i=1}^{n} t_i \qquad (1)$$

where ρ_i and t_i are the density and thickness of the ith layer, respectively, n is the total number of layers and T is the total thickness of the sequence. The number of layers and their thicknesses may be taken directly from seismic velocity-structure models; the problem is to find a means of estimating the layer densities. We have approached this problem in three ways.

Some ophiolites, at least, are now believed to be slices of oceanic crust and upper mantle. The velocity structures of the Semail Ophiolite, Oman and the Bay of Islands Complex, Newfoundland, for example, have been reconstructed on the basis of laboratory studies[14–16]. The principal lithologies present in the 'crustal' sections of ophiolites are basalts, diabases, gabbros and their metamorphic equivalents. A much simplified lithologic sequence, viewed from the top downward, consists of extrusive, generally pillowed, basalts (1–1.5 km thick), sheeted diabase dykes (1–1.5 km), and a high-level isotropic gabbro sequence (up to 1 km), which grades downward into a 3–5-km thick sequence of mafic, layered gabbros (hornblende, pyroxene, and olivine gabbro, troctolite, and so on) in which the ultramafic component typically increases with depth. The mafic gabbros are commonly, but not always, interlayered with ultramafic cumulates in the lower part of the 'crustal' section.

The velocity structures of ophiolites are similar to the velocity structure of the oceanic crust[14,15,17]. In ophiolites, 'layer 2' is characterized by strong velocity gradients which extend well into the sheeted dykes and reflect the combined effects of a systematic increase in metamorphic grade (zeolite to upper greenschist facies) and a systematic decrease in grain-boundary porosity with depth[14–17]. Velocities typical of oceanic layer 3 are encountered in the middle to lower part of the dyke sequence, where upper greenschist assemblages give way to those of lower amphibolite grade. The velocity gradient below this level is relatively low, and differences between ophiolites in the amount of modal olivine present in the lower part of the gabbro sequence account for the observed variability of layer 3 velocity structures[16].

In method 1, to estimate crustal density, we assume that layer 2 consists of basalts and dyke rocks in about equal proportions. The upper part of layer 3 is taken to consist of gabbro and metagabbro, with denser, olivine gabbros occurring in the lower half the layer. Neglecting the effect of interlayered ultramafic rocks in the lowermost part of the crustal section, we have used

Table 1 Densities of ophiolite samples

Lithology		No. of samples	Density (Mg m^{-3})
Metabasalt, basalt and spilite	(B)	34	2.73±0.09
Diabase and metadiabase	(D)	31	2.85±0.07
Metagabbro	(MG)	27	2.90±0.07
Gabbro and olivine gabbro	(G+OG)	38	2.95±0.07
Metagabbro, gabbro and olivine gabbro	(G+MG+OG)	65	2.93±0.07

† Thickness of layer taken from the average structure of Christensen and Salisbury[4].

‡ Calculated standard deviations do not include the effect of variability in crustal structure.

published water-saturated bulk densities[14–17] to estimate the mean densities of pertinent combinations of rock types given in Table 1.

Assigning densities to velocity structure models on the basis of ophiolite lithostratigraphy neglects the large-scale porosity of layer 2a (refs 7, 8), and is based on a lithologic model which is only loosely tied to the velocity structure. A preferable approach is one in which layer densities can be calculated from a statistically-valid, functional relationship between formation density and seismic velocity.

Assuming that the variation of grain properties is small relative to the difference between the properties of the grains and those of the pore medium (seawater), we may combine the theoretical density and time-average relations for two-component systems, to obtain a velocity/density function

$$\rho = a + b/V_p \qquad (2)$$

Fitting this equation to the laboratory densities and P-wave velocities (measured at 100 MPa) of samples recovered by the Deep Sea Drilling Project and from ophiolites[14–21] (Fig. 1) yields

$$\rho(\mathrm{Mg\,m^{-3}}) = (3.81 \pm 0.02) - (5.99 \pm 0.11)/V_p(\mathrm{km\,s^{-1}}) \qquad (3)$$

with a coefficient of determination (r^2) of 0.86 and an r.m.s. error of 0.07 Mg m^{-3}. Equation (3) describes the velocity/density relation for oceanic rocks very well.

In method 2 layer densities are calculated from seismic velocities according to equation (3). The relation does not account for increasing confining pressure, but the effect of pressure (above 100 MPa) on density and velocity is relatively small. Equation (3) reflects the effects of grain-boundary porosity and metamorphic grade, but also includes effects of alteration[18–19], which is not representative of oceanic basalts. This method also fails to account for large-scale porosity. Thus method 2 may be applied to deeper levels of the crust where porosity is low, but cannot be applied with confidence to oceanic layer 2.

Seismic velocities in porous media depend on the shapes of the voids as well as the properties of the matrix and pore medium. Because the shapes of large-scale voids in layer 2 are unknown, there are likely to be large uncertainties in the any postulated relationship between velocity and density or porosity[5]. We have, therefore, taken the simplest possible approach of calculating the coefficients of equation (2) from the properties of an average, zero-porosity basalt and the properties of seawater ($\rho = 1.025$ Mg m^{-3}; $V_p = 1.5$ km s^{-1}). The average bulk-grain densities of oceanic basalts range from 2.9 to 3.0 Mg m^{-3} (refs 7, 10, 12); we estimate the properties of a typical, zero-porosity basalt to be $\rho = 2.03 \pm 0.06$ Mg m^{-3} and $V_p = 6.65 \pm 0.20$ km s^{-1}. The velocity/density relation is then

$$\rho(\mathrm{Mg\,m^{-3}}) = (3.50 \pm 0.2) - (3.79 \pm 0.1)/V_p(\mathrm{km\,s^{-1}}) \qquad (4)$$

The velocity/density relation for the porous basalt formation (equation (4)) and for the laboratory data (equation (3)) are shown in Fig. 2.

Also shown in Fig. 2 are velocities and densities estimated from downhole logging in igneous basement at a number of

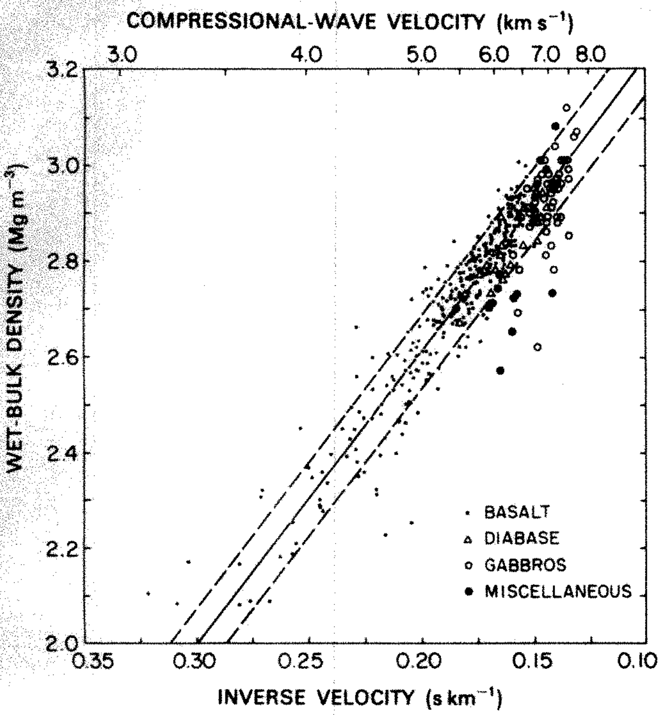

Fig. 1 Compressional-wave velocity versus wet-bulk density of basalts, diabases and gabbroic rocks sampled from ophiolites and recovered from the sea floor by drilling. Also included are some rock types (including serpentinites and amphiliolites) thought to be present but not abundant in the oceanic crust. Solid line represents least-squares fit (equation 3). Dashed lines represent standard error. The r.m.s. misfits to basalt, diabase and gabbro data taken separately range from 0.04 to 0.08 Mg m^{-3}.

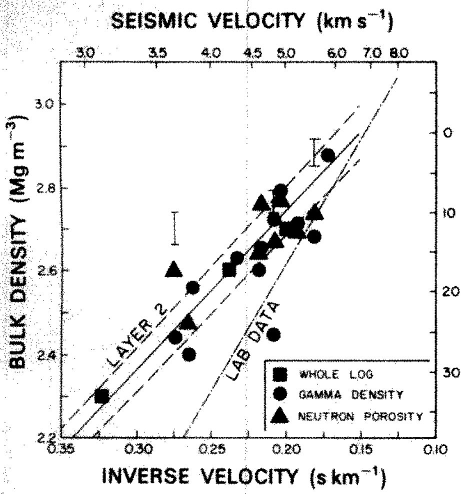

Fig. 2 Approximate velocity–density–porosity relation for a porous basalt formation (layer 2) and best-fitting relation for laboratory data. Also shown are formation velocities, densities and porosities estimated from downhole logs. Bars indicate porosities estimated from wide-spacing resistivity data[23].

DSDP sites. Some of the data are from published reports[8,11,22]. We have made additional, preliminary analyses of logs from holes 504B (Leg 83), 556, 558 and 564. The velocities shown are averages from sonic logs. Gamma–gamma density, neutron porosity and electrical resistivity data[23] have been used to estimate densities and porosities. The neutron porosity values have been corrected for pressure and bound water content as described by Kirkpatrick[8]. Some of the data points represent averages over the entire logged interval; in other cases (such as, Leg 83, 504B) the data points represent different intervals such as layers 2a, 2b and 2c. While we must emphasize that our interpretations of the logs are preliminary, and, therefore, subject to (presumably) minor changes, we find that the data correspond quite well with the predicted relation. The r.m.s. misfits of equation (4) to the log values of density and porosity are 0.06 Mg m^{-3} and 4%, respectively. Insofar is it does agree with available downhole logging data, equation (4) represents a valid means of estimating both the porosity and the density of layer 2 from seismic refraction data.

A particularly important point is that equation (4) predicts markedly higher densities than does the velocity–density relation based on laboratory measurements (equation (3)). For a seismic velocity of 5.0 km s^{-1}, the difference is ~0.15 Mg m^{-3}, for a velocity typical of layer 2a, about 3.75 km s^{-1}, the difference is 0.3 Mg m^{-3}. Thus the common practice of using laboratory data to estimate formation densities from seismic velocities may lead to serious errors when the porosity of the layer is greater than the grain-boundary porosity of the rocks.

In method 3, we have accounted for large-scale porosity of layer 2a by calculating layer densities according to equation (4) when the seismic velocity is <6.65 km s^{-1}. Thus, in general, equation (4) applies to oceanic layer 2. For velocities >6.65 km s^{-1} (layer 3), we have used equation (3).

Any of the three methods outlined above can be applied to an individual refraction survey. Because our objective is to estimate the average density of the oceanic crust, we have used several average velocity structures: three 'standard' three-layer models[4,24,25]; the type I and II sonobouy models of Christensen and Salisbury[4], in which layer 3 is subdivided into two units (3a and 3b); the Atlantic and Pacific multilayer models proposed by Houtz and Ewing[6]; and a four-layer model suggested by Purdy[13] for crust 140 Myr old. The velocity structures, estimated layer densities and mean crustal densities are summarized in Table 2.

A remarkable feature of the results is that the different velocity-structure models yield such similar mean crustal densities: the range of values found by method 1 is 2.89–2.91 Mg m^{-3}, the range for method 2 is, in general, 2.84–2.86 Mg m^{-3}, and most of the densities calculated by method 3 are in the range 2.88–2.90 Mg m^{-3}. Mean crustal densities estimated by methods 1 and 3 are also remarkably similar; the average difference is <0.01 Mg m^{-3}. Method 2 yields mean densities which are systematically lower by ~0.03 Mg m^{-3}. Having calculated the density structures by these methods, the problem is to select the best model.

Method 3 is preferable to the other methods because densities are calculated from the seismic structure, and the large-scale porosity of layer 2 is taken into account. Equation (4) used to estimate the density of layer 2 is also in good general agreement with the results of downhole logging in igneous basement (Fig. 2). Furthermore, the density structures calculated by this method are consistent with the inferred variation of physical properties with depth in the oceanic crust.

Large-scale porosity is generally restricted to the uppermost 400 m (layer 2a) of the section. Below that depth, the porosity is markedly reduced (layer 2b), and below 1,000 m (layers 2c and 3) porosity is apparently restricted to the grain boundaries[6,11,13,23]. Consequently, calculated layer densities (Table 2) should correspond to the densities of corresponding lithologies. Calculated layer 3 densities agree with the mean density of oceanic gabbros (2.93 ± 0.07 Mg m^{-3}). The density of the lower part of layer 2 (2.88) is higher than the mean (2.85 Mg m^{-3}), but agrees with the modal value (2.88 Mg m^{-3}) for diabases. The mean densities of different suites of oceanic basalts range from 2.79 to 2.80 Mg m^{-3} (refs 7, 10, 12). The range of calculated layer 2 mean densities (not included in Table 2) is 2.80–2.75 Mg m^{-3}. These values range downward from the mean for basalts and diabases because of the porosity of layer 2a, but the effect of porosity on the average density of layer 2 is reduced because the porous region occupies only ~20% of the layer thickness.

Thus, we conclude that density structures calculated by method 3 are representative of *in situ* densities in the oceanic crust. A reasonable mean density is 2.89 ± 0.04 Mg m^{-3}. Even if we assume that 500 m of ultramafic cumulates having a density of 3.20 Mg m^{-3} should be included, the mean crustal density is only 2.91 Mg m^{-3}. The proposed existence of a low-velocity layer of partially serpentinized periodotites at the base of the crust[26] would not significantly affect its density because the density of periodotites containing 50% serpentine is ~2.9 Mg m^{-3} (ref. 27). Including a 500-m blanket of sediments having a mean density of 2.0 Mg m^{-3} reduces the density of the entire crust to ~2.85 Mg m^{-3}.

Growing season precipitation from D/H ratios of Eastern White Pine

J. R. Lawrence* & J. W. C. White

Lamont-Doherty Geological Observatory of Columbia University, Palisades, New York 10964, USA

The search for climatic information from the hydrogen and oxygen isotope analysis of tree rings has produced mixed results[1–6]. Systematic changes in the D/H ratio with changing climate have been demonstrated[7], although relationships between climate change and the D/H ratio in tree rings from a single tree have been claimed, the interpretation of these data still causes controversy. Here we report that there is a strong correlation between both the D/H ratio of summer rain and tree ring cellulose from Eastern White Pine (*Pinus strobus* L.), and the amount of precipitation between May and August.

There are three major difficulties in interpreting the isotope composition of tree ring cellulose. (1) Organic matter is isotopically inhomogeneous[4,7–11]. (2) Complex biological, biochemical and hydrological processes take place during the growth of a tree[7,12–15]. (3) Isotope variations in precipitation from year to year at a single location have not been clearly related to temperature changes, except perhaps for those that accompany significant changes in the polar ice caps[16–18]. We have avoided the problem of the isotopic inhomogeneity of organic matter by analysing only carbon-bound hydrogen from cellulose[7]. Our studies of the complex isotopic fractionations resulting from biological, biochemical and hydrological processes in Eastern White Pine are reported elsewhere[19,20]. They demonstrate that the average hydrogen isotope composition of rain that falls during the growing season, May-August, can be found in tree rings of Eastern White Pine growing under highly restricted water supply conditions. Such trees mostly use soil moisture obtained from summer precipitation and therefore retain only a summer climate signal.

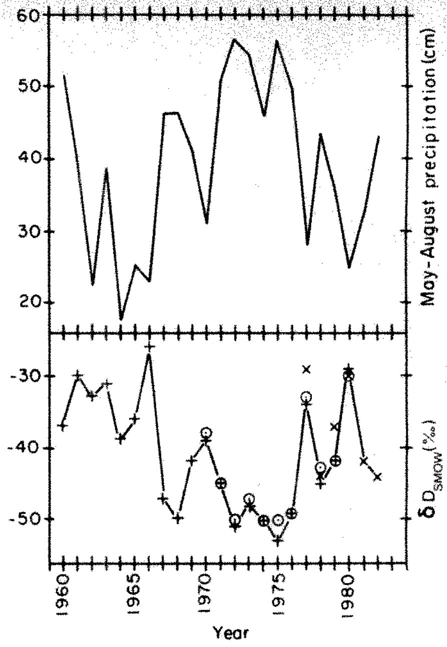

Fig. 1 Average amount of precipitation for the period May–August for five meteorological stations (Mohonk Lake, Poughkeepsie, Ellenville, Gardiner and Rosendale) plotted as a function of time. The δD values of rain and carbon-bound hydrogen from tree rings of two Eastern White Pine trees are also plotted. One tree covers the period 1960–80 (+), the other the period 1970–80 (○) and the rain from 1977–82 (×). The correlation coefficients between the δD values and the amount of May to August precipitation are −0.76, −0.93 and −0.88 respectively.

One climate signal that has been observed from stable isotopes in the precipitation from lower latitudes, is the inverse relationship between the δD and $\delta^{18}O$ of rain and the amount of precipitation. ($\delta D = [(D/H \text{ sample})/(D/H \text{ SMOW} - 1)] \times 10^3$, where SMOW is standard mean ocean water.) This 'amount effect' was observed by Dansgaard[21] when evaluating monthly precipitation samples obtained and analysed by the International Atomic Energy Agency (IAEA). He observed that isotopic ratios were "low in rainy months and high in months with sparse rain". He stated: "this 'amount effect' is found all the year round at most tropical stations, and in the summer time at mid latitudes", this rain being predominantly produced by convective storms. We also detected this amount effect during the present investigation.

Our sampling location, Mohonk Lake, New York, is located ~130 km north of New York City on the Schawangunk ridge on the west side of the Hudson Valley near New Paltz, New York. The two Eastern White Pine trees studied are located on a talus slope where groundwater has not been detected in the tree sap[20]. The trees are ~5 m high, 60 cm in diameter and >200-yr old.

The δD values of the rings from these trees together with the unweighted average δD value of all the individual rainfalls between May and August are plotted as a function of time in Fig. 1. One tree (no. 1) covers the period 1960–80, the other tree (no. 2) 1970–80 and the rains from 1977 to 1982. Also shown in Fig. 1 is the total amount of rain that fell between May and August of each year. These quantities represent the averages of five rain recording stations in the vicinity of Mohonk Lake.

An inverse relationship can be seen between the amount of precipitation and the isotope data (Fig. 1): years of high precipi-

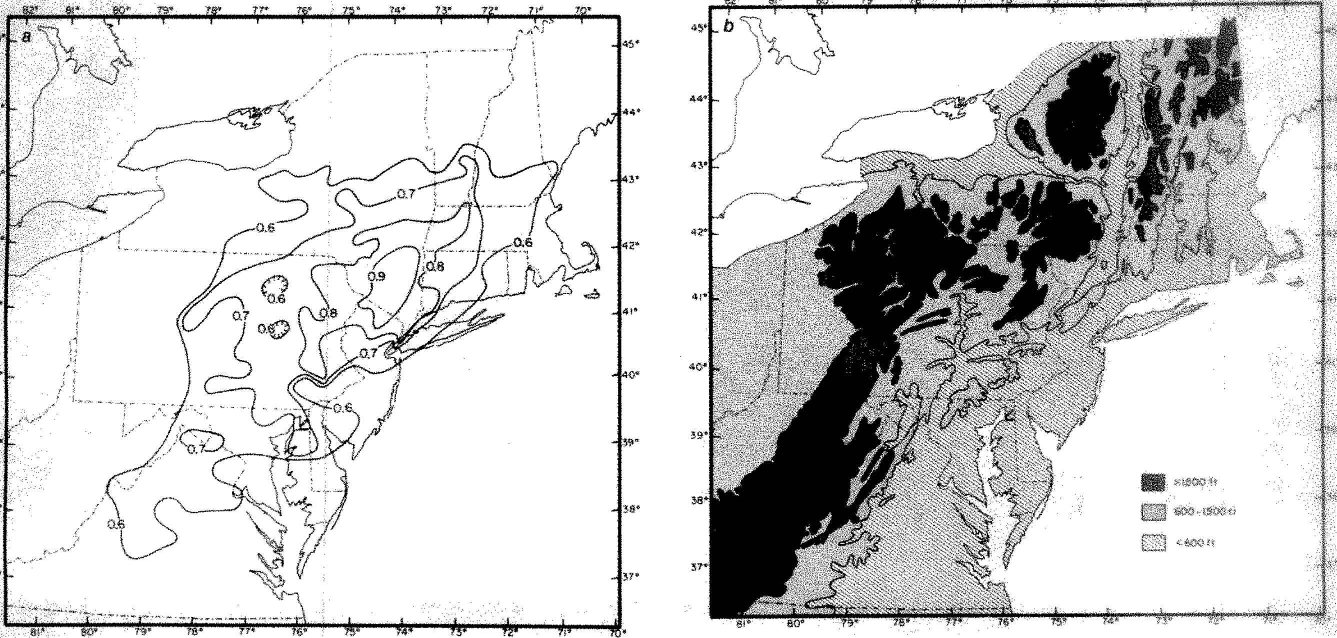
* Present address: Department of Geological Sciences, University of Houston, Texas 77004, USA.



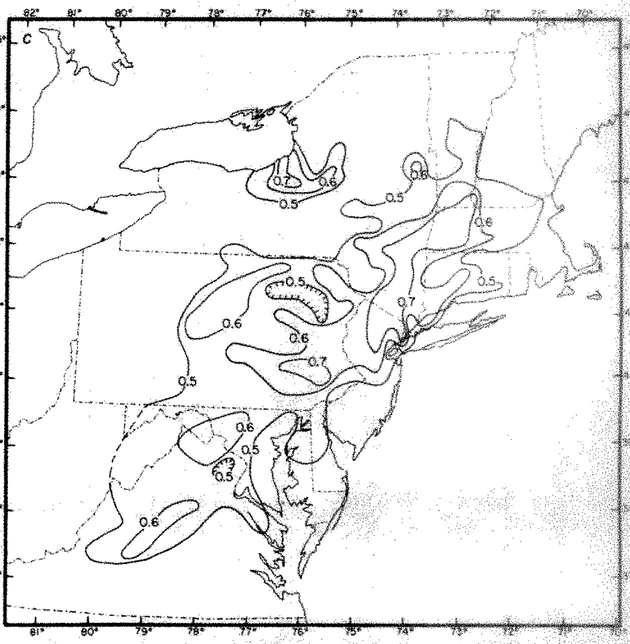


Fig. 2 *a*, Contours of correlation coefficients between the average amount of precipitation for May to August for the five stations given in Fig. 1 for the period 1960–82 and the amount of precipitation for the same time period for 181 stations around the northeastern US. After reduction in the degrees of freedom for persistence in the time series[22] the correlation coefficient contours, 0.6 and 0.7, are significant to better than the 95% confidence level. The contours >0.7 are significant to better than the 99% confidence level. *b*, The topography of the northeastern US showing elevation breaks at 600 and 1,500 feet. *c*, Contours of correlation coefficients between the δD values of carbon-bound hydrogen in the tree rings of the tree covering the period 1960–80 (see Fig. 1) and the average δD value (unweighted) of rainfall from May to August for the years 1981 and 1982 (23 δD values for the period 1960–82) and the amount of rain for May to August at 181 meteorological stations around the northeast US for the same 23-yr period. After reduction for the degrees of freedom in the time series[22] the correlation coefficient contours shown are significant to better than the 95% confidence level.

tation are marked by low δD values and vice versa. There is excellent agreement between the separate isotope data sets. The correlation coefficient between the mean δD value of the rain and the amount of precipitation for the 6 yr when samples were collected is −0.88. For the tree where 11 rings were analysed, the correlation coefficient is −0.93. For the tree covering 21 yr the correlation coefficient is −0.76. Each of these three paired sets of data were checked for persistence (autocorrelation)[22]. After reduction in the number of degrees of freedom, the three correlation coefficients were found to be significant to better than the 95%, 99% and 99% confidence levels respectively. The precipitation data show that the early 1960s had low rainfall whereas the mid-1970s had high rainfall. The isotope data only provide an indication of rainfall amounts during the warmer months, but there was a severe drought during the early 1960s, and during the mid-1970s the climate was wet, as demonstrated by the high level of reservoirs at the time[23]. Individual years of low rainfall during the relatively wet periods stand out—see 1980, 1977 and 1970 in Fig. 1.

The correlation coefficient between the δD of the tree rings and the amount of precipitation during the growing season applies to the immediate area around Mohonk Lake. To get a better idea of the regional extent of this isotope–precipitation relationship, additional correlations were attempted with meteorological stations around the northeastern US. First, the average May to August precipitation amounts from the five stations in the vicinity of Mohonk Lake for the period 1960–82 were correlated with precipitation amounts for the same 4 months and 23 yr for stations around northeastern US. A total of 181 correlation coefficients were calculated. The results (shown in Fig. 2*a*) show that topography and proximity to the ocean may be important (Fig. 2*b*). Correlations drop markedly near the ocean and are generally lower over mountain areas. Lower-lying areas excluding near shore areas have higher correlation coefficients.

A similar regional correlation picture (Fig. 2*c*) was constructed using the isotope data from tree 1 for the period 1960–80 and 2 yr (1981 and 1982) of rain isotope data. The isotopic results for this 23-yr period were correlated with precipitation during May–August for the same 181 stations as used in the precipitation correlations. The patterns are very similar to those observed in Fig. 2*a*.

Our results suggest that δD values of carbon-bound hydrogen from tree rings of Eastern White Pine growing in water-restricted conditions can be used to study past summer precipitation patterns. The region covered by our studies is primarily the

Hudson Valley and bordering areas. Because the relationship between the δD values of rain and the amount of precipitation during the growing season should apply to other areas in the eastern US, isotopic studies of trees in such areas might also reveal distinctive precipitation patterns with time. Combining results from several trees in different areas would then not only give variations of growing-season precipitation for individual areas but would also give the historical distribution of precipitation in both a spatial and temporal sense. Such a picture would be useful for understanding long-term changes in atmospheric circulation particularly for the warmer months of the year.

The isotope technique for obtaining climate information from tree rings of Eastern White Pine has certain advantages including that the hydrogen isotope climate signal is derived from the precipitation itself, and thus contains information about atmospheric processes. Future research will give a better picture of the causes of changes in the isotope ratios. For example, it has been shown that the isotopic composition of precipitation is influenced by the positions of storm tracks[24]. Oxygen isotopic analyses of Eastern White Pine when combined with hydrogen isotope analyses show considerable promise in providing a relative humidity signal[19]; the use of both isotopes should therefore prove highly valuable. The combined use of these isotope techniques with standard ring width techniques looks even more promising.

Induction of hair growth by implantation of cultured dermal papilla cells

C. A. B. Jahoda*, K. A. Horne & R. F. Oliver

Department of Biological Sciences, University of Dundee,
Dundee DD1 4HN, UK

Mammalian hairs are formed by differentiation and keratinization of cells produced in the epidermal matrix (Figs 3, 4). Using the rodent vibrissa follicle as a model[1], transplantation studies have shown that the dermal papilla, a discrete population of specialized fibroblasts, is of prime importance in the growth of hair[2,3]. Papillae induce hair growth when implanted into follicles[4,5] and can interact with skin epidermis to form new hair follicles[6]. When grown in culture, papilla cells display singular morphological and behavioural characteristics compared with connective tissue cells from other skin sources[7,8]. We report here that serially cultured adult papilla cells can induce the growth of hair when implanted into follicles which otherwise would not grow hairs. This finding presents an opportunity to characterize properties distinguishing the papilla cell population from other skin fibroblasts, and, more specifically, those which control hair growth. The eventual application of this work to human hair replacement techniques can also be envisaged.

We have cultured dermal papillae from adult rats. When the cells reach confluence, they form aggregates (Fig. 1) and can be serially cultured[7,8]. We have shown previously that discrete, freshly dissected papillae induce hair growth when implanted into the bases of follicles from which the lower halves with their original papillae have been removed[4]. Such follicles (Fig. 2) would not otherwise produce hairs[4,9,10]. In the present studies, we used similarly prepared follicles to evaluate the inductive capacity of cultured papilla cells when implanted as pellets into the bases of follicles from which the lower halves had been removed. Skin fibroblasts of early passage numbers (1–4) were used as control implants. After 4 weeks, hairs emerged from 28 (53%) of the follicles which had received papilla cells of early passage numbers (1–3), and those follicles kept under observation produced generations of hairs in a normal cyclic fashion.

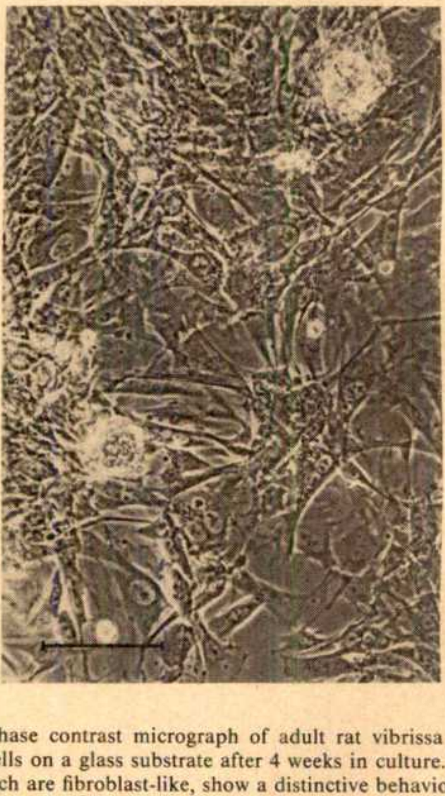

Fig. 1 Phase contrast micrograph of adult rat vibrissa dermal papilla cells on a glass substrate after 4 weeks in culture. Papilla cells, which are fibroblast-like, show a distinctive behaviour both in explant culture[7] and after passaging[8] and, in contrast to skin fibroblasts, tend to form clumps or aggregates on reaching confluence. Using a stereoscopic microscope, intact, epidermal cell-free dermal papillae dissected from the lower regions of vibrissa follicles, which had been excised from the upper lip of adult inbred hooded PVGC rats, were cultured as described previously[7,8]. Between 5 and 30 papillae were cultured at any one time as explants in Cruickshank culture chambers at 37 °C in an atmosphere of 5% CO_2–95% air in Eagle's minimal essential medium (Gibco) supplemented with 15–20% fetal calf serum (Gibco). The medium was changed every 3 or 4 days and on reaching confluence the cells were serially transferred to 35-mm dishes. Adult skin fibroblasts, derived from skin explants, were similarly grown in culture. Scale bar, 100 μm.

---

* Present address: Laboratoire de Zoologie, Université de Grenoble I, France.

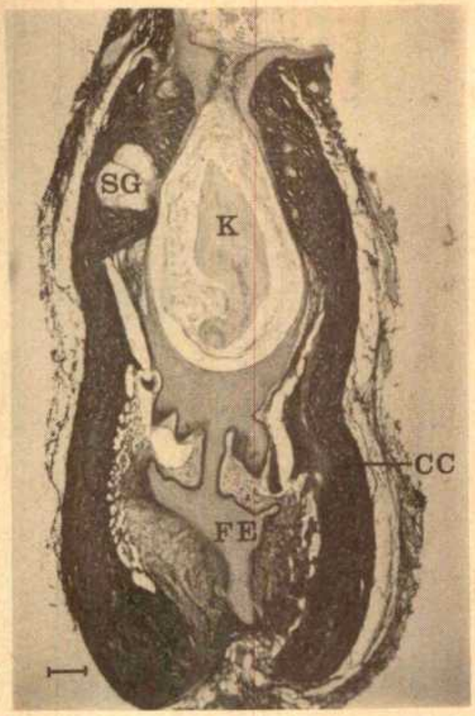

Fig. 2 Longitudinal section of a control vibrissa follicle from which approximately the lower half of the follicle has been removed. No subsequent hair growth has occurred and, near the bottom, remaining follicular epidermis (FE) has reverted to a solid column of outer root sheath cells. A loose plug of keratin (K) is visible near the top of the follicle adjacent to the sebaceous gland (SG). Vibrissa follicles are enclosed by a thick collagenous capsule (CC) the cut edge of which can be seen at the bottom. Vibrissa follicles, which are clearly arranged in a well defined pattern[9], were exposed by reflecting the whisker pad on the upper lip and the follicles selected for operation were identified. Lengths of follicle, including the entire bulb and enclosed papilla, were removed with a transverse cut to leave half or less of the upper region of each follicle *in situ* and the pad was stitched back into position[4]. An identical procedure was used to prepare follicles to receive either cultured papilla cell or fibroblast implants. Following biopsy, follicles were serially sectioned for histological examination. Scale bar, 100 μm.

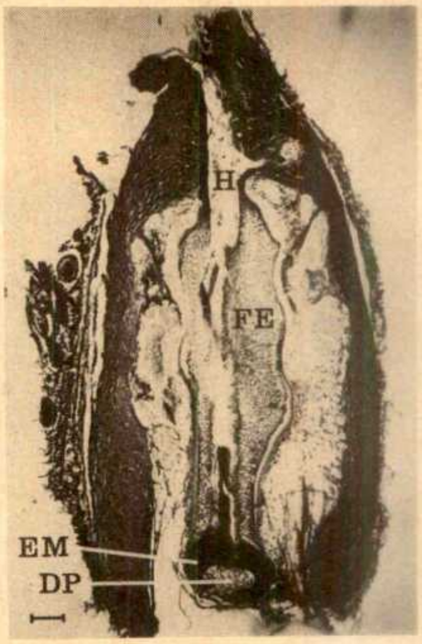

Fig. 3 The upper half of a vibrissa follicle into the base of which cultured dermal papilla cells had been implanted. Follicular epidermis (FE) has become organized around the new dermal papilla (DP) and has formed a basophilic epidermal matrix (EM) which is actively producing hair (H). Papilla cells scraped from culture dishes and divided into small pellets were inserted into the bases of the exposed follicular epidermis following removal of the lower halves of the follicles. Scale bar, 100 μm.

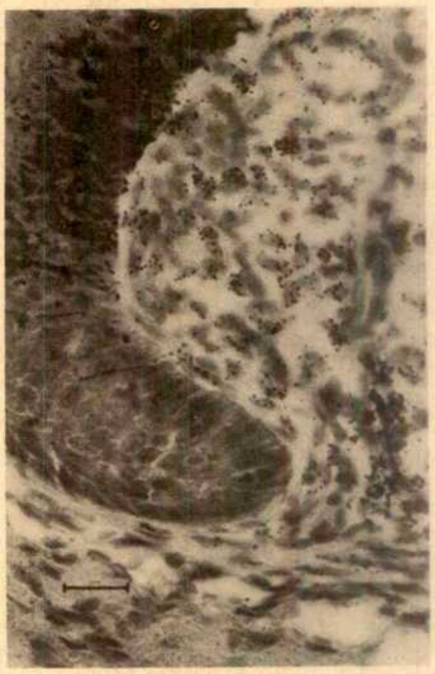

Fig. 4 Autoradiograph showing detail of the bulb region of a follicle actively growing hair 28 days after implantation of papilla cells which had been labelled in culture with a total dose of 2 μCi of ^{3}H-labelled thymidine. Labelling is restricted to cells in the dermal papilla and its basal stalk with no evidence of labelling in the surrounding connective tissue cells. Part of the epidermal matrix is shown on the left-hand side. Scale bar, 20 μm.

In contrast, no hairs emerged either from amputated follicles which had not received papilla cell implants (Fig. 2) or from follicles into which cultured skin fibroblasts had been implanted.

Histological examination revealed the presence of a new bulb at the site of papilla cell implantation, with an epidermal matrix organized around a discrete dermal papilla (Fig. 3). Further evidence that the new papilla originated from implanted papilla cells was obtained by autoradiographic examination of follicles where implanted papilla cells were labelled with ^{3}H-thymidine (Fig. 4). Thus we have shown that the original papilla cell mass can form a functional dermal papilla which interacts with follicular epidermis, resulting in the organization of a new, hair-producing bulb. By demonstrating that cultured papilla cells retain their ability to elicit hair growth, the specific properties of papilla cells which operate to modulate follicular epidermal cell activity and thus control the growth of hair can now be analysed and characterized *in vitro*. One such approach would be to compare profiles of the characteristics of papilla cells of early passage numbers (1–3) with those of later passage number cells (10–15), which appear to lose their inductive ability, and with skin fibroblasts. Work is in progress to determine the stage at which the functional capacity of papilla cells in culture is irretrievably lost.

With the recent culture of follicular epidermal cells[11], it will be possible also to study the influence of papilla cells (which retain some of their *in situ* traits when grown alone in culture[8]) on epidermal proliferation and differentiation. Although it has been shown that epidermal and dermal cell suspensions from newborn mouse skin are capable of reforming hair follicles when transplanted into adult animals[12], it is unclear whether at this stage of skin development all dermal cells are still capable of being involved in follicle reformation. We suggest that in adult animals, skin fibroblast cells from non-follicular dermis are incapable of performing the same role as dermal papilla cells.

Finally, recent advances in cell culture of individual dermal and epidermal follicle components have importance for the study of human hair disease and hair loss as well as for dermal–epidermal interactions. In particular the culture of human hair dermal papilla cells[13] means that, for example, the effects of hormones on the dermal component can now be examined. Our demonstration that dermal papilla cells which have divided can still promote active hair growth, and our recent finding that cultured papilla cells can induce hair follicle formation when associated with non-hair-forming embryonic epidermis (C.A.B.J., unpublished data), raises the possibility of using cell culture techniques to increase dermal papilla cell numbers as part of a human hair transplant process.

We thank Mr G. Coghill for performing the autoradiography. This work was supported by MRC studentship.

Monoclonal antibodies define differential *ras* gene expression in malignant and benign colonic diseases

A. Thor, P. Horan Hand, D. Wunderlich, A. Caruso, R. Muraro & J. Schlom

Laboratory of Tumor Immunology and Biology,
National Cancer Institute, National Institutes of Health, Bethesda,
Maryland 20205, USA

DNAs of some human tumours can transform NIH 3T3 fibroblast cells[1–7], thus demonstrating the transforming potential of human *ras* genes (Hu-*ras*^{Ha}, Hu-*ras*^{Ki}, and Hu-*ras*^{N}, respectively Harvey, Kirsten and neuroblastoma *ras* genes). Only a small percentage of a given type of human carcinoma, however, scores positive in this assay system[8–10]. Activation of *ras* and subsequent transformation of NIH 3T3 cells are either by a point mutation in the *ras* gene[11–18] or enhanced expression of the normal, or proto-onc, *ras* gene[19–21]. If the transformation of a given human tumour involves the enhanced expression of the normal or cellular *ras* gene and the resulting gene product, the tumour DNA would probably score negative in the NIH 3T3 transfection assay. In human colon carcinoma, for example, lesions at position 12 of Hu-*ras*^{Ki} have been found[8,21]. None of nine colon carcinomas obtained at biopsy, however, contain the *ras* lesion at this position, using a Hu-*ras*^{Ha} probe[22]; one other colon carcinoma does appear to contain amplified proto-onc *ras*[21], and other colon carcinomas do have increased levels of *ras* RNA[23]. There are at least three explanations for these observations. Either very few colon carcinomas contain point-mutated *ras*, the lesion in the majority of colon carcinomas is at a position other than 12, or *ras* activation in many colon carcinomas involves the enhanced expression of either the point-mutated or proto-onc form of a *ras* gene. We have now used monoclonal antibodies directed against a synthetic peptide reflecting sequences of the human T24 *ras* gene product to define *ras* p21 protein expression in a spectrum of colonic disease states. Immunohistochemical analyses of individual cells within tissue sections reveal differences in *ras* p21 expression in colon carcinomas compared with normal colonic epithelium, benign colon tumours and inflammatory or dysplastic colon lesions. Our data suggest that *ras* p21 expression is correlated with depth of carcinoma within the bowel wall, and is probably a relatively late event in colon carcinogenesis.

Monoclonal antibodies directed against human tumour-associated antigens have proved extremely useful in understanding the human neoplastic process and in defining differences between human malignant and normal cell populations. Immunohistochemical techniques using formalin fixed tissue sections and monoclonal antibodies have been used to identify different cell populations within a given tumour mass, which is particularly useful in the study of human carcinomas, such as colon carcinoma.

We have developed recently a series of monoclonal antibodies that are immunoreactive with the human *ras* 21,000 molecular weight (MW) gene product, p21. The immunogen used was a synthetic peptide reflecting positions 10–17 of the Hu-*ras* protein product from the T24 bladder carcinoma[24]. The antibodies designated RAP (for *ras* peptide) one to five[24], react with both the T24 Hu-*ras* peptide and the Hu-*ras*^{Ha} peptide (which differ in a single amino acid at position 12 of the p21 molecule, Val for Gly, respectively[17]) using solid phase radioimmunoassays. They also immunoreact with a 21,000 MW protein in both T24 bladder carcinoma cells[15] and rat mammary tumours containing activated *ras*[25,26]. We have shown also that denaturation of cell extracts or tissue sections with formalin or glutaraldehyde enhanced detection of *ras* p21 by the RAP monoclonal antibodies[24]; this was expected, as the amino acids at positions 10–17 are predicted to sequester within the tertiary structure of the p21 molecule[27,28]. We report here studies using the RAP antibodies to determine whether any biological correlations exist between enhanced *ras* p21 expression (either the point-mutated

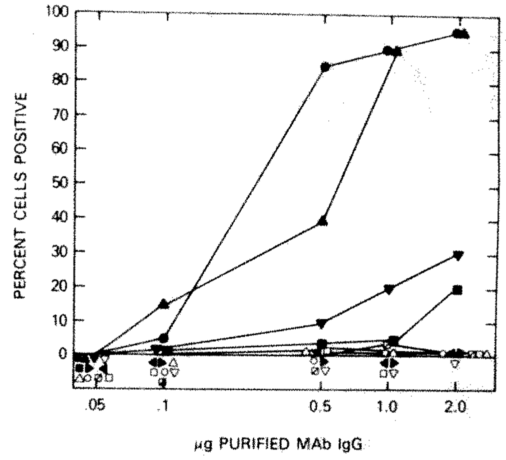

Fig. 1 Titration of purified antibody RAP-5 (in μg purified IgG per 200 μl) with formalin fixed colonic tissues. Serial sections of adenocarcinomas of the colon (solid symbols), tubulovillous adenomas (open and slashed squares), tubular adenomas (open triangles) and normal colonic epithelium (open circles) were assayed for *ras* p21 using the ABC immunoperoxidase technique[49,50] and purified IgG[51] of RAP-5. (Histologically, tubular adenomas demonstrate branching tubules embedded in the lamina propria, and tubulovillous adenomas are mixtures of tubular and villous patterns[43]). The % of positive cells is a semiquantitative value (evaluated twice independently) determined by tumour cells scoring *ras* positive divided by the total tumour cells × 100 (for carcinomas and adenomas), and the % normal colonic epithelial cells is determined by dividing *ras* positive epithelial cells by the total number of normal colonic epithelial cells × 100. For all tissues used in this study a control IgG2a isotype identical primary antibody (UPC-10)[52] was used at the same immunoglobulin concentrations as the RAP antibodies and no positivity was demonstrated.

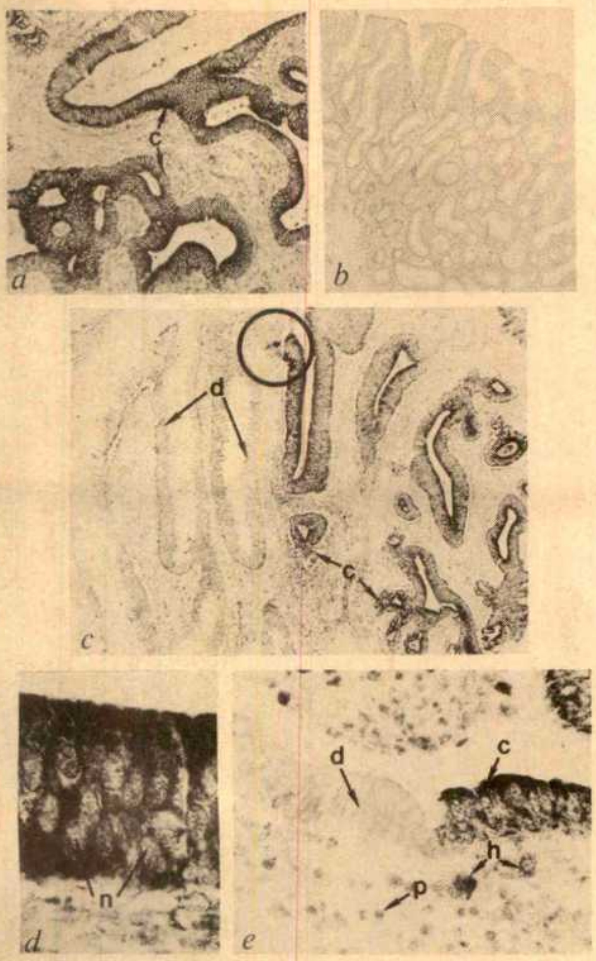

Fig. 2 Immunoperoxidase staining of colon lesions by RAP-1. RAP-1 (at a 1:8 dilution of supernatant fluid) was reacted with formalin fixed paraffin embedded human tissues using the ABC immunoperoxidase method. *a*, Adenocarcinoma of the colon (invasive, ×130). The dark regions reflect the reaction of the diaminobenzidine substrate and thus antibody binding to cytoplasmic *ras* p21 in carcinoma (c) cells. The lighter region is the haematoxylin counter stain, showing no antibody reactivity. *b*, Tubulovillous adenoma (×38). Dysplastic colonic epithelium, stroma and a mixed inflammatory mononuclear cell infiltrate are negative. *c*, Colonic adenocarcinoma (×130); mild dysplasia (d) and invasive carcinoma (c) arising in a patient with a 20-yr history of ulcerative colitis. Weak basal positivity with RAP-1 of mildly dysplastic cells is seen (circle) adjacent to strongly staining cells which are severely dysplastic and/or carcinoma *in situ*. *d*, A higher magnification (×540) of *c* demonstrating cells expressing large quantities of *ras* p21 with disorganized architecture and enlarged anaplastic nuclei (n) in the zone of severe dysplasia and/or carcinoma *in situ*. *e*, A transition zone (other than seen in *d*) of mild dysplasia (d), adjacent to carcinoma *in situ* (c) expressing high levels of *ras* p21. Note the negative submucosal stroma and plasma cells (p) and the positive histiocytes (h) (×540).

or proto-onc form) within individual cell types in a spectrum of colonic disease states.

5 μm-thick sections of formalin fixed colon carcinomas were assayed for Hu-*ras* p21 content using purified immunoglobulin preparations of monoclonal antibody RAP-5 and the ABC immunoperoxidase method. Using a 40-fold range of purified antibody and serial sections of tumours, four of the six colon carcinomas are clearly positive for *ras* p21 expression (Fig. 1). The cell type expressing *ras* in these sections is the malignant epithelium (Fig. 2*a*), with the number of positive carcinoma cells ranging from 20% to 90% (Fig. 1); the number of reactive cells could be reduced in a linear fashion by decreasing the concentration of the RAP antibody used. Colonic stroma and smooth muscle are negative for *ras* p21. Normal colonic mucosa from carcinoma patients (when seen within the same section containing carcinoma cells) is either negative for reactivity with RAP-5 at all immunoglobulin concentrations used, or demonstrates less than 1% of normal epithelial cells expressing *ras* p21. Normal colonic epithelium from a non-cancer patient also contains less than 1% positive cells at all RAP-5 concentrations (Fig. 1).

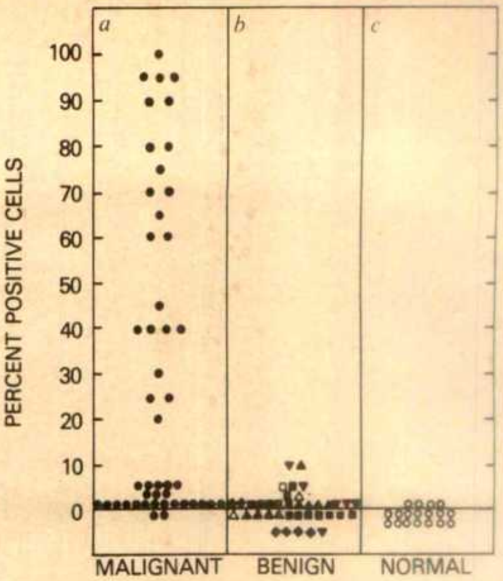

Fig. 3 Reactivity of RAP-1 with various colonic disease states. RAP-1 (at a 1:8 dilution of supernatant fluid) was reacted with formalin fixed 5-μm sections of colonic adenocarcinomas (*a*, closed circles), diverticulitis (*b*, inverted triangles), tubular adenomas (*b*, squares), tubulovillous adenomas (*b*, triangles), ulcerative colitis (*b*, diamond), hamartomatous polyp (*b*, open square), inflammatory bowel disease, not otherwise specified (*b*, open triangle), and normal colon (*c*, open circles), using the ABC immunoperoxidase method. Each symbol represents a tumour or tissue from a different patient. The % positive cells denotes the number of tumour cells scoring *ras* p21 positive divided by the total number of tumour cells × 100 in carcinomas and benign tumours (*a*, *b*) and denotes the number of epithelial cells scoring *ras* p21 positive divided by the total number of epithelial cells × 100 in diverticulitis and inflammatory bowel disease (*b*) and normal colon (*c*). RAP-1 and RAP-5 gave similar results in these studies.

Four benign colon tumours (two tubular and two tubulovillous adenomas) were also assayed for *ras* p21 expression using identical RAP-5 concentrations and assay conditions to those described above. Both types of lesions have been implicated as potentially premalignant[29,30], with a higher incidence of carcinoma arising from tubulovillous adenomas[31-33]. The tumour cells from all four polyps assayed are either negative for RAP binding or contain only a few cells positive over the 40-fold range of antibody concentrations used (Figs 1 and 2*b*).

To further define if biological correlations exist in *ras* p21 expression, 47 colon carcinomas, 38 benign colon tumours, inflammatory or dysplastic colon lesions, and 18 specimens of normal colon from non-cancer patients were examined for reactivity with antibody RAP-1. Of the 47 carcinomas, 45 contain some *ras* positive carcinoma cells; however, a distinction could be observed (Fig. 3*a*) with 23/47 (49%) of the tumours from individual cancer patients containing greater than 20% of tumour cells expressing *ras* p21 at the antibody concentration used. In contrast, 4 of the 18 normal colon samples from non-cancer patients contain ≤1% positive cells with the remainder scoring negative (Fig. 3*c*). Several types of benign, dysplastic or inflammatory colon lesions were also assayed (Fig. 3*b*). Of these 38 lesions, 36 are either negative for *ras* p21 expression or contain ≤5% of tumour or epithelial cells scoring positive, with the remaining two lesions containing 10% positive cells. We conclude that at the RAP antibody concentration and conditions used for these assays, enhanced *ras* p21 expression can be observed (using >20% cells positive as an arbitrary criterion, Fig. 3) in 23 of 47 colon carcinomas, as opposed to none of 38

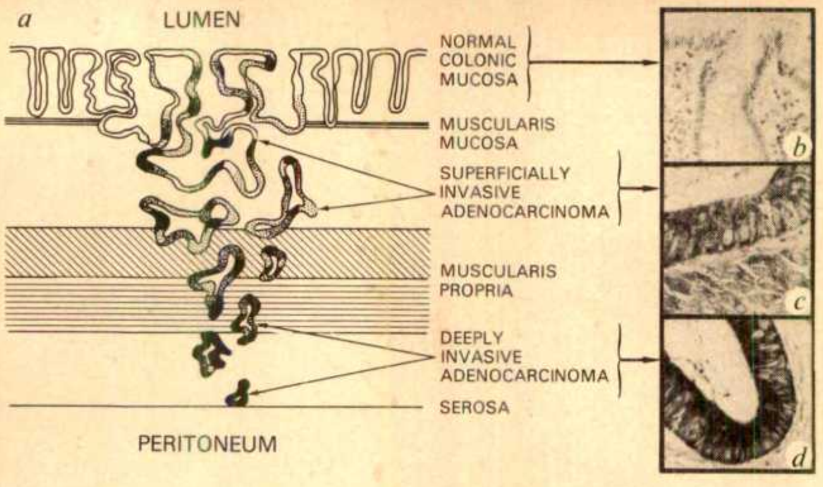

Fig. 4 Correlation between depth of colon carcinoma invasion and *ras* p21 expression. *a*, Schematic representation of a serial section of the bowel wall with the various histological layers, dysplastic and carcinomatous structures identified. Representative immunoperoxidase staining of these various structures with RAP-1 is depicted by the strong (dark) expression of *ras* p21 in deeply invasive glands versus the lesser amount of *ras* p21 expression (lighter shading) in more superficial glands. *b*–*d*, The different areas of a single tissue section containing all areas represented schematically in *a*. *b*, Normal colonic mucosa (×220). The epithelium and stroma are negative. There is a weak reactivity of tissue histiocytes. *c*, Superficially invasive adenocarcinoma (×330). Tumour cell heterogeneity and weak reactivity for *ras* p21 are demonstrated *d*, Deeply invasive adenocarcinoma (×220). Subserosal tumour demonstrates intense expression of *ras* p21.

benign colon tumours, dysplastic or inflammatory lesions, or 18 normal colon specimens (all from different patients). The immunoassays reported here should be termed 'group specific' for Hu-*ras*, in that they identify determinants shared by a group of related genes (Ha, Ki, N) within a given species[34]. The development of additional immunological reagents to 'class specific' and 'type specific' epitopes reflecting the more variable regions of this gene family, and molecular probes reflecting these variable regions, will be required to answer questions as to which tumours or cells within a given tumour mass are expressing a specific *ras* gene.

Much antigenic heterogeneity has been observed within most human carcinomas using monoclonal antibodies directed against several distinct tumour associated antigens[35]. We find that virtually all colon carcinoma specimens also vary in the per cent of tumour cells within a given tumour mass expressing *ras* p21 (Fig. 3*a*). It is interesting that *ras* activation defined by DNA transfection occurs in only one of five melanoma cell lines derived from independent metastatic foci of a single patient[36]. We used RAP-5 to examine five metastatic lesions from two colon carcinoma patients whose primary tumours were positive for *ras* p21 expression (40% and 80% of tumour cells, respectively). All five metastatic lesions (to ovary, liver, omentum and two lymph nodes) also displayed antigenic heterogeneity, with levels ranging from 5% to >90% of cells scoring positive for *ras* p21 expression. There are several possible explanations for this observed heterogeneity in *ras* expression. (1) The assays used may not be sensitive enough to detect low levels of *ras* expression in some cells; (2) the cell cycle may influence p21 expression (as seen in other tumour-associated antigens[37] and *ras*[38]); (3) the milieu of individual tumour cells or tumour cell clusters including autocrine, paracrine and/or endocrine factors may influence *ras* expression; (4) *ras* may not be involved in the aetiology of colon cancer; its expression could be an effect of the neoplastic process in some cells or lesions. Alternatively, it may be involved in the initial transformation event, but other mechanisms of conferring immortality may come into play in the approximately 10 to 30 years that elapse between the initial cell transformation and the detection and removal of a carcinoma mass[39,40].

There is much evidence that many carcinomas arise from premalignant disease states such as adenomas, familial adenomatous polyposis, or ulcerative colitis[41–43]. If such a multistep process is involved in colon carcinogenesis, it would be of interest to determine where in this process enhanced *ras* expression is detected. Figure 2 shows examples of invasive carcinoma in a pseudopolyp of an ulcerative colitis patient (Fig. 2*c*, *e*). The dysplastic epithelial cells of the pseudopolyp here react weakly with the RAP antibody. In contrast, adjacent cells (which are more severely dysplastic and/or carcinoma *in situ*) express comparatively high levels of *ras* p21. We conclude that *ras* activation, at least in these carcinomas, may be a relatively late event in the transformation process[10,44,45].

The degree of malignancy (potential for metastasis) of a colon carcinoma correlates with the depth of tumour invasion through the bowel wall (from the muscularis mucosa to the serosa) (Fig. 4*a*)[46–48]. This invasion may occur via the infiltration of individual tumour cells through the stromal elements and musculature of the bowel wall; these cells are believed to subsequently divide and form individual tumour cell clusters with various degrees of glandular organization. We identified specimens from three colon cancer patients in which benign colonic mucosa, as well as the depth of invasion of tumour cell clusters, could be evaluated for each patient. In these samples, normal colonic mucosa are either negative or express extremely low levels ($\leq 1\%$ of cells) of Hu-*ras* p21 (Fig. 4*b*). Superficially invasive carcinoma cells show intermediate levels of Hu-*ras* p21 (Fig. 4*c*), whereas deeply invasive tumour cell clusters (Fig. 4*d*) show the highest levels of *ras* p21 in the tumour mass. Thus, in each of the three cases in which the depth of individual dysplastic and malignant tumour cell clusters could be evaluated, enhanced Hu-*ras* p21 expression detected by RAP-1 correlate with depth of tumour invasion.

Whether *ras* gene activation is actually involved in the aetiology of human colon cancer remains to be proven. The immunological studies reported here do, however, provide evidence that *ras* p21 is differentially expressed in many malignant colon carcinomas compared with benign colon tumours, dysplastic or inflammatory lesions and normal colon. Furthermore, enhanced *ras* expression appears to correlate with the depth of invasion (presumed degree of malignancy) in at least some colon carcinoma lesions, and also appears to be a relatively late event, at least within some lesions, in the multi-step process of colon carcinogenesis.

We thank K. McNaughton, A. Sloan, M. Ballard, J. Knapp, D. Poole, M. Taylor, E. Smith, P. Freeman and L. Otsby for technical assistance and Dr M. Weeks for helpful discussions.

T3-Ti receptor triggering of T8+ suppressor T cells leads to unresponsiveness to interleukin-2

Armand Bensussan, Oreste Acuto, Rebecca E. Hussey, Claudio Milanese & Ellis L. Reinherz

Division of Tumour Immunology, Dana-Farber Cancer Institute and the Departments of Medicine and Pathology, Harvard Medical School, Boston, Massachusetts 02115, USA

T3-associated disulphide linked heterodimers (Ti_n) comprised of clonally unique α-chains of molecular weight (MW) 49,000–54,000 and β chains of MW 43,000 have been identified as the antigen receptors on human cytotoxic effector and inducer T-lymphocytes[1–3]. Crosslinking of Ti molecules by either the appropriate nominal antigen/MHC specificity or anti-clonotypic monoclonal antibody results in clonal expansion of such cells via induction of IL-2 receptor expression, endogenous IL-2 release and IL-2-IL-2 receptor interaction[4]. To determine whether analogous antigen receptor molecules and autocrine growth mechanisms are utilized by suppressor T-cells[5–7], we produced an anti-clonotypic monoclonal antibody against a non-cytotoxic T8+ suppressor T-cell, T8AC6, which defines a T3-associated disulphide-linked heterodimer of similar molecular weight to the above clonotypes. We find that T3-Ti triggering of suppressor clones (T8AC6, T8AC7 or T8RW) does not result in IL-2 production or T-cell proliferation and in contrast to inducer clones, also leads to a transient IL-2 unresponsive state. We suggest that such T3-Ti receptor mediated autoregulation of suppressor T-cell growth is necessary in the facilitation of initial inducer T-cell activation following antigenic perturbation.

We derived human suppressor T-cells T8AC6 and T8AC7 by stimulating autologous peripheral blood mononuclear cells (PBMC) of a healthy ragweed antigen (RWAGE) atopic donor with an MHC restricted/RWAGE-antigen specific inducer T-cell termed RW17C[3] and cloned in a two-layer agar system as previously described[8]. This strategy was employed because earlier studies indicated that such stimulation results in both autoreactive T4+ amplifier T-cells and noncytotoxic T8+ clones[8]. A third suppressor clone (T8RW) was obtained from direct stimulation of PBMC with RWAGE at the end of the fall hay fever season. We propagated these T-cell clones *in vitro* with IL-2 and irradiated autologous PBMC for more than 14 months, maintaining stable phenotype (T1+T3+T4−T8+T11+T12+) and function. To determine whether the T8+ clones were capable of suppressing the secretion of immunoglobulin by a combination of B-cells and RW17C T-cells stimulated with RWAGE, we added increasing numbers of T8AC6, T8AC7 or T8RW to the autologous T-B-cell mixture consisting of 5×10^4 T4+RW17C T-cells in the presence of RWAGE. This mixture produces 18 μg ml^{-1} of IgG without additional cells (Fig. 1). In the absence of RW17C, B-cells with or without RWAGE produces less than 200 ng of IgG per ml (data not shown). Addition of increasing numbers of T8+ cells results in marked suppression of IgG secretion. For example, when as little as 6.2×10^3 cloned T8-cells were added, IgG secretion is reduced to 6–9 μg ml^{-1}, a reduction of more than 50%, and is reduced further when 12.5–50×10^3 T8+ T-cells were added.

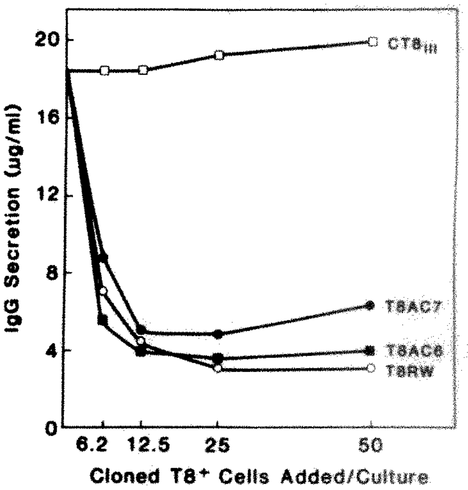

Fig. 1 Regulatory activities of T8+ T-cell clones. Human T8+ T-cells T8AC6 and T8AC7 were derived by stimulating PBMC of a healthy atopic donor with an irradiated autologous antigen/MHC restricted T4+ inducer RW17C and cloning in a semi-solid system as described previously[8]. T8RW was obtained by an identical technique from RWAGE stimulated PBMC of the same donor. Individual colonies were expanded in liquid culture by restimulating with irradiated (5,000 rad) autologous PBMC and IL-2 containing supernatants. Further cloning was performed (×2) by limiting dilution technique at 0.3 cells per well. Clones were maintained in IL-2 and also placed on irradiated autologous PMBC on a feeder layer every 3 weeks. $CT8_{III}$ is an extensively characterized alloreactive T8+ T-cell clone derived from the same donor and was utilized as a control[1]. Varying numbers of T8+ cloned cells (6.2×10^3 to 50×10^3) were added to a culture consisting of 50×10^3 autologous B cells (E rosette negative PBMC treated with anti-T4, anti-T8, anti-Mo1 and rabbit complement)[16], 2.5×10^3 macrophages, 50×10^3 RW17C and the specific antigen RWAGE (final concentration: 5 μg ml^{-1}) (Worthington Diagnostics[3]). The cultures were performed in a total volume of 0.2 ml in 96 well round-bottomed microtitre plates (Costar) in RPMI 1640 (Gibco) containing 10% FCS (M.A. Bioproducts). After 7 days' incubation at 37 °C in a humidified atmosphere containing 7% CO_2 in air, the wells were harvested by pooling the cells and supernatants from triplicate wells and storing at −20 °C prior to assay of IgG synthesis. Solid phase RIA was performed as previously described[18].

To eliminate the possibility that the inhibition of immunoglobulin production is due to an unspecific crowding effect of cells in the culture system, an autologous alloreactive cytotoxic T-cell clone, $CT8_{III}$, was added to the mixture of RW17C T-cells and B-cells. In contrast to the effect of the three other clones (T8AC6, T8AC7 and T8RW), increasing $CT8_{III}$ concentration has no effect on IgG secretion by RW17C and B-cells (Fig. 1). We conclude that the suppressive activity of T8+ clones in this system is not mediating via a trivial crowding mechanism.

We then investigated whether clonotypic structures on T8+ suppressor T-cell clones were similar to those identified on T4+ inducer clones and class I and class II specific CTL clones. We

Table 1 Influence of various monoclonal antibodies on IL-2 proliferative responses of clones T8AC6 and T4AC3

	Pretreatment of clone T8AC6					
Stimulus	Medium	Anti-T3	Anti-Ti_5	Anti-Ti_6	Anti-T4	Anti-T8
Medium	480	398	456	506	511	413
IL-2	27,312	5,301	6,205	29,312	28,049	28,506
	Pretreatment of clone T4AC3					
Stimulus	Medium	Anti-T3	Anti-Ti_5	Anti-Ti_6	Anti-T4	Anti-T8
Medium	140	153	190	192	201	141
IL-2	16,912	26,281	17,412	27,266	18,733	17,854

3×10^4 T8AC6 or T4AC3 cells were incubated in round-bottomed microtitre wells (Costar) with either media or monoclonal antibody (final dilution 1:1,000 in culture medium). 30 h later, purified 0.5 IL-2 U ml^{-1} (provided by Dr K. A. Smith, Dartmouth Medical School) was added[4]. After 24 h at 37 °C in humidified atmosphere containing 7% CO_2 in air, individual wells were pulsed with 0.2 μCi of ^{3}H-TR (Schwarz-Mann), collected 18 h later on a MASH II apparatus (M. J. Bioproducts) and ^{3}H-TdR incorporation was then measured in a β scintillation spectrometer. Each value represents the mean of triplicate samples with standard derivations in all experiments <15%. Anti-Ti_5 and anti-Ti_6 are the anti-clonotypic antibodies directed against T8AC6 and T4AC3, respectively. These IgG1 subclass monoclonal antibodies were also purified from malignant ascites with protein A Sepharose (Pharmacia) and coupled to swollen CnBr activated Sepharose 4B beads (Pharmacia) at 5 mg ml^{-1} for induction of clonal proliferation and IL-2 production[4]. Proliferative responses of 3×10^4 T8AC6 or 3×10^4 T4AC3 were as follows: (i) T8AC6: + medium, 392 c.p.m.; + Sepharose-linked anti-T3, 282 c.p.m.; + Sepharose-linked anti-Ti_5 314 c.p.m.; + Sepharose-linked anti-Ti_6, 416 c.p.m.; + Sepharose-linked anti-T4, 402 c.p.m.; + Sepharose-linked anti-T8, 511 c.p.m. (ii) T4AC3: + medium, 153 c.p.m.; + Sepharose-linked anti-T3, 19,373 c.p.m.; + Sepharose-linked anti-Ti_5, 198 c.p.m.; + Sepharose-linked anti-Ti_6, 15,219 c.p.m.; + Sepharose-linked anti-T4, 202 c.p.m.; + Sepharose-linked anti-T8, 186 c.p.m. To quantitate the amount of IL-2 secreted by T8AC6, T8AC7, T8RW, and T4AC3 after stimulation with Sepharose-linked anti-T3, a previously described murine T-cell proliferative assay was employed[4]. Specifically, 10^5 T-lymphocytes were incubated overnight at 37 °C with Sepharose-linked anti-T3 in a final volume of 0.5 ml. The supernatants were then collected, passed through 0.45 μ filters and added 1:1 (v/v) to 5×10^4 murine PHA T-lymphoblasts. After 18 h of culture, individual wells were pulsed for 24 h with 0.2 μCi of ^{3}H-TdR, mashed and counted. A standard curve obtained with serial dilutions of purified human IL-2 was used to quantitate the amounts of lymphokine produced by the various T-cell clones. Supernatants generated from T8AC6, <0.01 U ml^{-1}; T8AC7, <0.01 U ml^{-1}; T8RW, <0.01 U ml^{-1}; T4AC3, >0.20 U ml^{-1}.

developed a series of monoclonal antibodies directed at the T8AC6 suppressor T-cell clone by standard fusion techniques[9], and selected hybridoma cultures containing antibody reactive with T8AC6 but unreactive with Laz 509 (an autologous EBV transformed line). Supernatant from one individual hybridoma of approximately 800 tested contained antibody (anti-Ti_5, IgG1 murine isotype subclass) which did not react with resting or activated T-cells or a series of additional T8+ suppressor clones derived from the same individual ($n = 15$). This hybridoma was cloned and recloned by limiting dilution in the presence of feeder cells; malignant ascites were then developed.

Solubilized membrane preparations were obtained from the ^{125}I labelled T8AC6 clone in order to characterize the surface structure recognized by anti-Ti_5. SDS-PAGE electrophoresis of the molecule precipitated by anti-Ti_5 from ^{125}I labelled-T8AC6 in reducing conditions shows two bands of a 49,000 and 43,000 MW corresponding to the α- and β-chain respectively (Fig. 2, lane *a*). In nonreducing conditions this structure appears as a single band of 90,000 MW (Fig. 2, lane *c*), which demonstrates that the Ti_5 structure is a disulphide-linked heterodimer. The 90,000, 49,000 and 43,000 molecular weight species are not present in control immunoprecipitates with an irrelevant anticlonotype, anti-Ti_6 (Fig. 2, lanes *b* and *d*). Anti-Ti^5 does not precipitate material from a second T8+ suppressor clone T8AC7, derived from the same donor, thus confirming its non-crossreactive anticlonotypic specificity (data not shown).

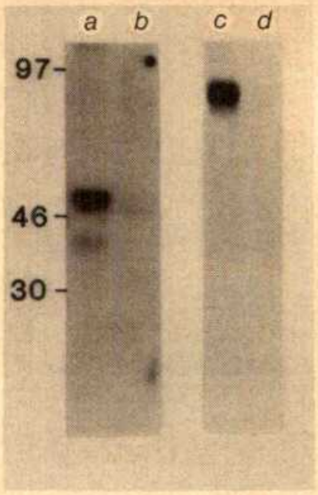

Fig. 2 SDS-PAGE of anti-Ti_5 immunoprecipitates from surface ^{125}I-labelled T8AC6 cells. Cells were surface labelled with ^{125}I (NEN) using a standard lactoperoxidase method[10]. Briefly, 2×10^7 viable, cells were washed with RPMI 1640, resuspended in PBS, and labelled with1 μCi ^{125}I for 15 min at room temperature, followed by the addition of 100 μl NaI (1 mol l^{-1}). Labelled cells were then harvested and washed three times in cold RPMI 1640. Cell lysate was prepared by resuspending the cell pellet in 300 μl RIPA buffer, *p*H 7.5, containing 1% Triton X-100, phenylmethylsulphonyl fluoride, and trypsin inhibitor and agitated for 40 min at 4 °C. Cell lysates were stored at −70 °C before use. Immune precipitations were carried out using preformed complexes of rabbit anti-mouse Ig and specific monoclonal antibody[19]. They were then washed 4 times with RIPA buffer as above and dissolved in SDS-polyacrylamide gell electrophoresis (SDS-PAGE) sample buffer and loaded onto separate slots on a 10% polyacrylamide slab gel. Identical aliquots of immune precipitates were run in reduced and nonreduced conditions. Gels were dried and radiolabelled precipitates were visualized using standard methods. *a*, Anti-Ti_3, reduced; *b*, negative control complex (anti-Ti_6, an irrelevant anticlonotypic antibody), reduced; *c*, anti-Ti_5, nonreduced; *d*, negative control complex (anti-Ti_6), non-reduced.

Previous studies with cytotoxic T cell clones indicate that the Ti structure is linked to the monomorphic 20,000 and 25,000 MW T3 molecules and comodulates with them[10]; we have therefore attempted to determine whether a similar noncovalent association exists between the Ti molecules on suppressor cells and T3. We preincubated T8AC6 cells with anti-T3 for 24 h at 37 °C and then washed them to remove free monoclonal antibodies. We subsequently analysed cell reactivity by indirect immunofluorescence (Epics V cell sorter) with a panel of monoclonal antibodies. Before modulation, we found that all T8AC6 cells are reactive with anti-T3 and anti-Ti_5 (Fig. 3). After modulation with anti-T3, however, T3 expression is reduced by 95%. Anti-T3 induced modulation also results in removal of the Ti_5 molecule, indicated by loss of anti-Ti_5 reactivity. This is not a non-specific effect, as we observe that T8 surface expression is not influenced by this process and IL-2 receptor expression (shown by anti-IL-2 R, a monoclonal antibody directed at the IL-2 receptor and with an identical distribution to anti-Tac) is enhanced. Our findings imply that suppressor T-cells have antigen receptor structures similar to those found on inducer and cytotoxic T-cells (T3-Ti molecular complexes).

We show here that the outcome of a given immune response is dependent on the relative number of T8+ suppressor and T4+ inducer T-cells (see also ref. 11). It is thus important to determine the signals required for T8+ suppressor T-cell growth. Earlier studies have shown that soluble or Sepharose bound anti-Ti (or anti-T3) monoclonal antibodies, like physiological ligand, enhanced proliferative responses of inducer and cytotoxic T-cells to purified IL-2 by inducing an increase in their surface IL-2 receptor expression[4]. Moreover, Sepharose-bound anti-Ti (or anti-T3) or physiological ligand triggers

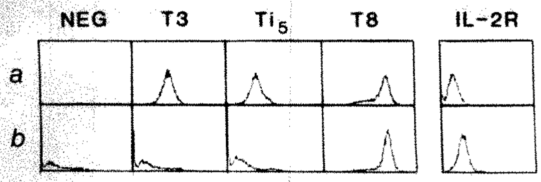

Fig. 3 The Ti structure of the T8+ T-cell suppressor clone T8AC6 comodulates with T3. T8AC6 cells were preincubated with media (*a*) or the monoclonal antibody anti-T3 (*b*) (final dilution 1:300) for 24 h at 37 °C and subsequently washed several times prior to analysis. Phenotypic analysis was performed by indirect immunofluorescence with fluorescence conjugated goat anti-mouse $F(ab')_2$ IgG. Samples were analysed with monoclonal antibodies (see designations above indicated histogram) on an Epics V cell sorter[10]. 10,000 cells were analysed in each sample. Each histogram displays the number of cells (ordinate) versus the intensity of fluorescence (abscissa) expressed on a logarithmic scale. The negative control used to determine background fluorescence was a 1:300 dilution of ascites derived from a nonreactive hybridoma (neg).

endogenous clonal IL-2 production in the absence of macrophages or feeder cells, leading subsequently to T-cell proliferation. This suggests that induction of IL-2 receptor expression, but not IL-2 release occurs with minimal T3-Ti receptor crosslinking and that antigen-induced proliferation of these cells is mediated through an autocrine pathway involving endogenous IL-2 production, release and subsequent binding to IL-2 receptors. We have performed similar experiments using T8+ suppressor T-cells. The representative T8+ suppressor clone (T8AC6) proliferates as well as the T4+ inducer clone T4AC3 to purified IL-2 (measured by ^{3}H-TdR incorporation) (Table 1). In the presence of soluble anti-T3 antibody, however, the IL-2 response of T8AC6 was virtually abolished (5, 301 vs. 27,312 cpm). Similarly, soluble anti-Ti_5 greatly reduces IL-2 responsiveness of T8AC6. An irrelevant anti-clonotype, (anti-Ti_6), or anti-T4 or anti-T8 antibodies have no effect on subsequent IL-2 responsiveness by T8AC6, and anti-Ti_5 has no effect on the response of the T4AC3 clone to IL-2. Hence the effects on T8 suppressor clones are specific and non-toxic. Furthermore, although the appropriate anti-clonotype and anti-T3 antibody inhibit IL-2 responsiveness of T8+ suppressor cells, they also enhance the IL-2 response of T4AC3 T4 inducer cells as previously observed (16,912 to 26,281-27,266 c.p.m.)[10]. This enhancement was observed at all anti-T3 and anti-Ti_6 antibody concentrations tested (10^{-2}-10^{-4} dilutions), and in either 0.1, 0.5 or 1 U ml^{-1} of IL-2. The inhibition of IL-2 responsiveness following soluble anti-T3 or anti-Ti preincubation of suppressor T-cells is not secondary to a failure of IL-2 receptor expression (Fig. 3).

One possible explanation of the inhibition is that such T3-Ti triggering results in an autoregulatory antagonist functional activity, in which case even T3-Ti receptor crosslinking with Sepharose-bound antibody would not initiate cell growth. We find that such Sepharose-bound anti-T3 and appropriate anti-Ti antibodies induce T4AC3 but not T8AC6 proliferation (Table 1). These antibodies stimulate IL-2 production from T4AC3 but not T8AC6, T8AC7 or T8RW. As crosslinking of T3/Ti molecules on suppressor T-cells does not result in autologous IL-2 production and clonal proliferation, it is not surprising that the same T8+ suppressor T-cells are unable to proliferate to the irradiated RW17C inducer T-cell utilized in the initial cloning procedure, autologous macrophages or B-cells (with or without RWAGE). The absence of a measurable proliferative response makes determination of the specificity and the target of an individual suppressor clone difficult. We plan experiments on regulation of immunoglobulin production with suppressor clones and isolated autologous and allogeneic lymphoid populations to address this issue.

Our results described here suggest that suppressor T-cells proliferate to IL-2 but that triggering of the T3-Ti complex on suppressor T-cells (with or without crosslinking) induces a state of IL-2 hyporesponsiveness. We also find that this refractory period is transient, persisting for only three to four days. Thus, the growth response of anti-Ti (or anti-T3)-treated T8AC6 compared to anti-T8-treated (control) T8AC6 cells is reduced by 80% at 24 h, 60% at 48 h, 30% at 72 h and 0% at 96 h. Such autoregulation of suppressor T-cell growth[12,13] may be necessary to facilitate inducer T-cell activation following initial antigenic pertubation. Once antigen is eliminated and T3-Ti stimulation abates, inducer T-cell-derived IL-2 can mediate clonal T8+ suppressor cell growth. Persistent amplification of the immune response would result in further T8+ suppressor cell expansion and hence appropriate termination of induction. Our future experiments will attempt to determine the targets and mechanism of suppression, and the relationship of the T3-Ti complex to any putative suppressor effector molecules which abolish immunoglobulin production in this or other unrelated systems[6,14,15]. We will also attempt to determine whether other types of suppressor T-cells are governed by similar mechanisms of growth regulation[16,17]. We thank Mr John Daley and Mr Herb Levine for technical assistance with the Epics V cell sorter. This work was supported by NIH grants R01 NS17182 and R01 AI19087-01. A.B. is a recipient of a research support grant from the French Medical Research Foundation.

Note added in proof: Monoclonal antibodies and heteroantisera have now been produced to clonotypes on T8RW and T8AC7 and precipitate characteristic disulphide-linked heterodimers.

A Ca-dependent Cl^- conductance in cultured mouse spinal neurones

David G. Owen, Menahem Segal & Jeffery L. Barker

Laboratory of Neurophysiology, National Institute of Neurological and Communicative Disorders and Stroke, National Institutes of Health, Bethesda, Maryland 20205, USA

Long-lasting conductance changes triggered either by brief (millisecond) electrical stimuli and/or entry of calcium ions have been observed in a variety of excitable tissues[1-4]. The electrical consequences of these events depend on the ion conductance affected and on the ion concentration gradient across the membrane, while the long-lasting nature of the change sustains the cell at either sub- or supra-threshold levels for activation of regenerative action potentials. We report here that many cultured mouse spinal neurones exhibit a voltage-activated chloride conductance that lasts for seconds and is dependent on extracellular calcium, $[Ca^{2+}]_o$. This conductance may repolarize and stabilize the cell at a level subthreshold for generating action potentials, thus complementing the functional roles of Ca-dependent K^+ conductances[5-8].

Neurones were cultured from the embryonic mouse spinal cord according to methods published previously[9]. After 3-4 weeks in culture, we studied the cells at 23 °C with intracellular recording and two-electrode voltage-clamp techniques (Fig. 1). Most of our experiments used CsCl-filled microelectrodes and bathing media containing tetraethylammonium (TEA) in order

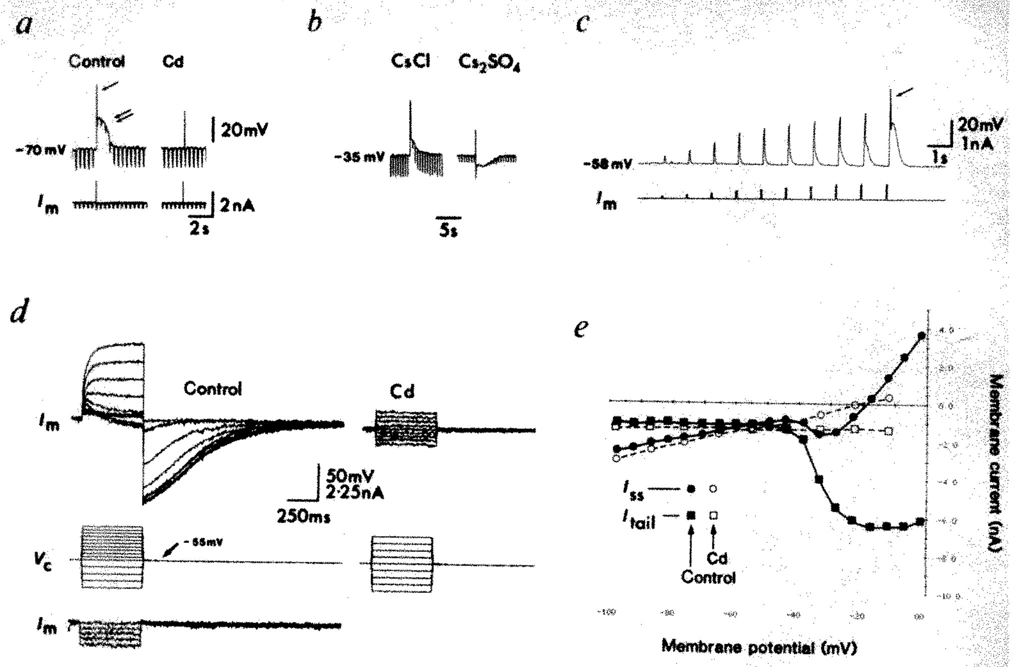

Fig. 1 A slow Ca^{2+}- and Cl^--dependent conductance is present in cultured mouse spinal neurones. ***a***, Records made using a KCl-filled electrode. Left trace: A 50-ms depolarizing current step evokes a Ca spike (single arrow) and long-lasting ('slow') afterdepolarization (double arrow). Voltage deflections in response to constant-amplitude hyperpolarizing current pulses (I_m) reveal an increase in membrane conductance during the afterdepolarization. Right trace: Both events are abolished when 0.2 mM Cd^{2+} is applied by pressure ejection. ***b***, Voltage responses to 50-ms depolarizing current steps at a holding potential (maintained with d.c. current injection) of −35 mV. A depolarizing response is recorded with a CsCl-filled electrode (left trace) while a hyperpolarizing response is triggered with Cs_2SO_4-filled electrodes (right trace). Downward voltage deflections are in response to hyperpolarizing constant current injections and indicate sizeable increases in membrane conductance during both responses. ***c***, Voltage responses (upper trace) recorded with a CsCl-filled electrode in response to depolarizing constant current steps of increasing amplitude (I_m). Activation of the long-lasting depolarizing response occurs in a graded manner and precedes the generation of a Ca spike (indicated by single arrow). ***d***, Voltage-clamp analysis of the same cell shown in *c* using two CsCl-filled electrodes. Membrane currents (I_m) in response to voltage commands (V_c) in normal bathing medium (left) and in the presence of Cd (right). For clarity, control current records (left) are separated according to the polarity of the commands, with responses to hyperpolarizing command voltage steps shown in the lower traces and responses to depolarizing steps in the upper traces. Voltage commands and data acquisition were controlled with a PDP-11/23 computer. Current and voltage were digitized at 250 Hz and for display purposes individual data points are connected by lines. ***e***, Current–voltage (I–V) relationships for data obtained from *d*. Currents were measured at the end of the 500-ms voltage steps (steady-state currents, I_{ss}) and immediately after returning to the holding potential (I_{tail}), in the presence and absence of 0.1 mM Cd^{2+}. In all these experiments, microelectrodes contained either 3 M KCl, 3 M CsCl or 3 M Cs_2SO_4. The bathing medium consisted of (mM): 121 NaCl, 2.5 KCl, 4 $MgCl_2$, 4 $CaCl_2$, 5 HEPES, 10 glucose, 20 TEA-Cl and 0.5–1.0 µM TTX.

to block all outward potassium conductances[10,11]. In these conditions, 27 of 33 cells expressed the conductance described below, whereas with KCl-filled electrodes the conductance was detected less frequently (10 of 43 cells).

The conductance response was routinely elicited with brief depolarizing current steps to potentials more depolarized than −45 mV. When recording with KCl-filled electrodes, the response was usually associated with a 15–30 mV depolarization (from resting potentials of −60 to −70 mV) lasting a second or more and usually preceded by a rapid (about 100 ms) Ca^{2+} spike (Fig. 1*a*). Both the Ca^{2+} spike and the slow after-depolarization were eliminated by local application of cadmium (Fig. 1*a*) or cobalt ions. The polarity of the voltage change associated with the conductance response was sensitive to the counteranion in the microelectrode. A slow depolarizing conductance was consistently triggered in cells recorded with CsCl-filled electrodes, whereas a long-lasting hyperpolarizing response could be triggered in cells when recording with Cs_2SO_4-filled electrodes (Fig. 1*b*). The Cl^- gradient across the membrane is therefore important in determining the polarity of the response. A Ca-dependent action potential was not a prerequisite for triggering the conductance response, as activation of the slow depolarization frequently occurred in a graded manner and at membrane potentials negative to the threshold for generating a Ca-dependent action potential (Fig. 1*c*). The steady-state current–voltage (I–V) relationship (where the steady-state current was measured at the end of each 500-ms voltage step) of cells bathed in TEA and tetrodotoxin (TTX) and voltage-clamped with CsCl-filled electrodes was nonlinear over the range of membrane potentials −45 mV to 0 mV (Fig. 1*d*, *e*). Following voltage steps to potentials more depolarized than −45 mV, inward-going 'tail' currents were detectable on returning to the holding potential. Both the nonlinear properties of the steady-state I–V curve and the tail currents were eliminated in solutions nominally free of Ca^{2+} (not shown) or by application of either Cd^{2+} (Fig. 1*d*, *e*) or other Ca^{2+} conductance antagonists, including manganese, Co, nickel and D600, suggesting that Ca^{2+} entry is required for activation of the conductance.

The time-dependent currents generated during the depolarizing commands ('on response') and subsequent tail currents ('off response') probably reflect activation of a single ion conductance mechanism, because analysis of responses to voltage-clamp double-step protocols reveals that the I–V relations and reversal potentials (E_{rev}) for both 'on' and 'off' current responses are the same. E_{rev} cannot be measured directly in the recording conditions normally used (Cl^--loaded cells) because E_{rev} lies within the potential range for activation of the conductance. Extrapolated 'instantaneous' I–V relations of pairs of I (steady-state and tail currents) and V measurements taken from the data in Fig. 1*d*, however, give a reversal potential of −17.6 mV (s.e.m. = 0.8 mV, $n = 7$ pairs) and the result for a constant activation step (not shown) was −19.6 mV (s.e.m. = 0.2 mV, $n = 7$ pairs). The steady-state I–V relationship is linear in the −20 to 0 mV range and the amplitudes of the corresponding tail currents are maximal (Fig. 1*e*), suggesting that the conductance is fully activated in this range. The intercept of the I–V relationship over this range with either the passive I–V relations (extrapolated from data in the −79 mV to −55 mV range) or the I–V relationship in the presence of blocking concentrations of Cd^{2+} is −17 mV (Fig. 1*e*). This is consistent with our estimate of E_{rev} above. When maximally activated from a holding potential of −55 mV, the magnitude of the Ca-dependent conductance evoked in Fig. 1*d* was 150 nS (calculated from tail currents and assuming E_{rev} is −17 mV). This Ca-dependent conductance did not inactivate appreciably during depolarizing steps to between −20 and −10 mV for up to 10 s, as evidenced by the constancy of tail current amplitudes following depolarizing commands maintained for this period of time (not shown). Activation at −10 mV could be described by an exponential function with a single time constant of 70 ms (from tail current measurements). The decay of tail currents following repolarization of the membrane from the activation potential reflects deactivation of the

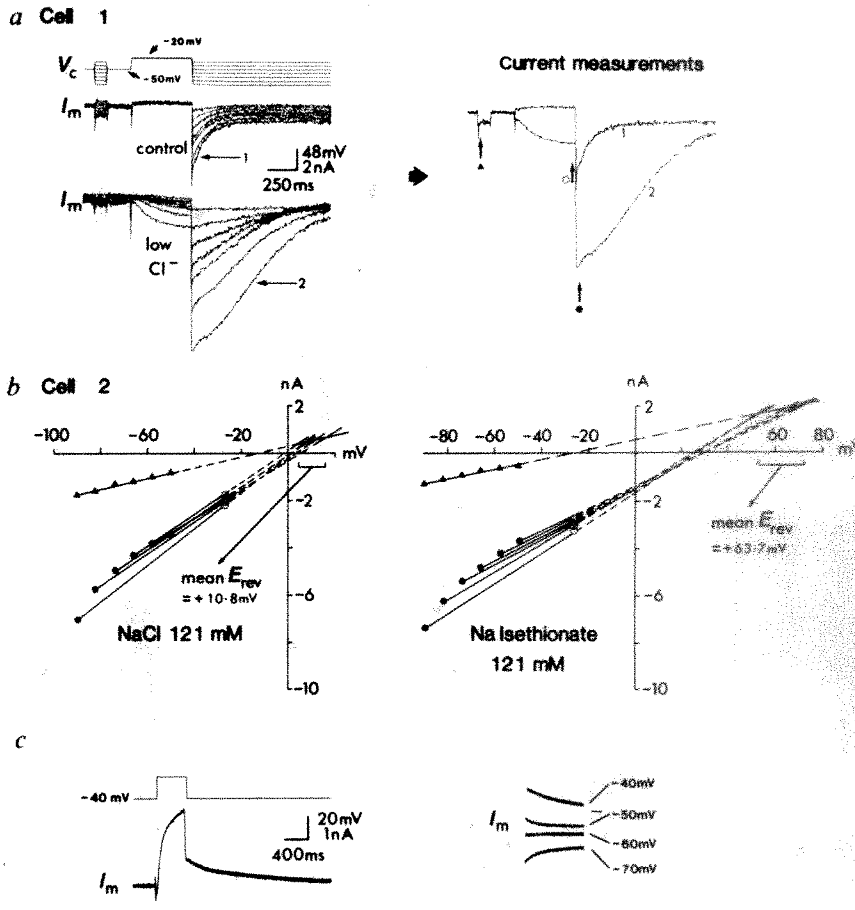

Fig. 2 Time-variant currents remaining in cells bathed in TTX and TEA and after Cs injection are sensitive to E_{Cl}. ***a***, Left panel, upper trace: a typical double-voltage-step protocol used to derive estimates of the reversal potential (E_{rev}) of tail currents evoked by a constant activation (depolarizing) voltage step. A series of *I* responses to *V* steps is superimposed. Middle trace: superimposed current responses, in normal bathing medium containing 158 mM Cl⁻. Lower trace: current responses obtained when Na isethionate was pressure-applied in the vicinity of the cell to reduce $[Cl^-]_0$ from 158 mM to about 37 mM. Right panel: two current records in response to the same voltage command are superimposed to emphasize the difference between the responses recorded in control (trace 1) and low $[Cl^-]_0$ (trace 2). When $[Cl^-]_0$ is reduced, current developed during the depolarizing step is reversed in direction, the tail current increases in amplitude and its decay slows. Current measurements were made as indicated by the arrows. Time-invariant or leak current is represented by triangles and instantaneous currents for the activated conductance state are represented by the open and closed circles. Instantaneous *I*-*V* relations were extrapolated to their intercept with that extrapolated from leakage or passive conductances in *b*. Use of such pairs of currents to make this estimate was justified by the identity of the conductance underlying the two components (I_{ss} and I_{tail}) and also necessitated by the lability inherent in both activation and driving force parameters. For example, the steady-state current during depolarization (○) was not necessarily constant, particularly in low $[Cl^-]_0$ (*a*, left panel, lower trace). *I*-*V* plots of the type shown in *b* revealed a progressive collapse of the driving force in this cell when bathed in low [Cl⁻] but with no apparent change in the degree of activation (not shown). ***b***, Leak *I*-*V* plots (currents measured before depolarizing voltage step: triangles) and chord *I*-*V* relationships (circles) following activation of the conductance with a depolarizing voltage step. Currents were sampled as indicated in *a*. These data were obtained from another cell for which the driving force was more stable and for which E_{rev} for GABA-activated currents was also calculated to monitor changes in the Cl⁻ gradient across the membrane. Left panel: E_{rev} in normal medium ($[Cl^-]_0 = 158$ mM) is estimated to be +10.8 mV (s.e.m. = 1.4 mV, $n = 6$ *I*-*V* pairs). Right panel: ambient NaCl was displaced by close application of Na isethionate in the vicinity of the recorded cell to reduce $[Cl^-]_0$, theoretically to a minimum of 37 mM. E_{rev} now extrapolates to +63.7 mV (s.e.m. = 3.2 mV, $n = 6$ *I*-*V* pairs), a change which somewhat exceeds that predicted from the Nernst relationship (that is, +37 mV), for a conductance involving solely Cl⁻ and assuming that the effective $[Cl^-]_0$ at the membrane is 37 mM. The shift in E_{rev} for GABA-activated current in this cell was about +40 mV (not shown). ***c***, Tail currents invert at about −60 mV when recording with Cs_2SO_4-filled electrodes. Left: activation of a slowly developing outward current by a command voltage step to −20 mV. Similar current responses in other cells were abolished in 0.2 mM Cd^{2+}. Right: tail currents measured, in the same cell, at different membrane potentials (indicated) following an activating (depolarizing) command voltage step. The polarity of the tail current reverses at about −60 mV.

conductance, since instantaneous *I*-*V* plots from varying times during tails indicate a progressive reduction in the membrane conductance rather than a change in the driving force for the current. Deactivation is apparently voltage-sensitive, being faster at more hyperpolarized potentials (Fig. 2*a*) and slower during prolonged or intense activation or with increased $[Ca^{2+}]_0$. This is consistent with the regulation of conductance by Ca^{2+} entry and saturation of Ca-sequestering mechanisms during prolonged or strong depolarizing commands.

This conductance mechanism superficially resembles Ca-dependent K^+ conductances recorded in a variety of excitable membranes in its apparent voltage-sensitivity, time course of activation and relative lack of inactivation[12,13]. The reversal potential for the current response is not consistent with a K^+-selective mechanism, however, nor is it consistent with a pure Ca^{2+} current, which would be expected to reverse at quite positive potentials[14]. E_{rev} is in fact identical to that of γ-aminobutyric acid (GABA)-activated Cl⁻ currents recorded in the same cells[15]. Ca-dependent 'nonspecific' cation currents, described for other preparations[16-18], also reverse in this potential region (about 0 mV).

We used a double-voltage-step protocol in different ionic conditions to estimate E_{rev} for tail currents (Fig. 2*a*). Neither complete replacement of extracellular Na^+ with choline, nor raising $[K^+]_0$ from 2.5 mM to 25 mM, nor raising $[Ca^{2+}]_0$ from 4 mM to 20 mM altered E_{rev} measured in this way. We did find, however, that replacement of much of the extracellular Cl⁻ by the impermeant anion isethionate[19] altered current responses evoked during depolarizing commands, changed the amplitude and time-course of tail currents (Fig. 2*a*) and shifted the estimated E_{rev} in a depolarizing direction (Fig. 2*b*). Replacement of Cl⁻ with isethionate also shifted E_{rev} for GABA-activated currents in a depolarizing direction in the same cell (not shown). Similar sizeable shifts in estimates of E_{rev} have been recorded using methane sulphonate to replace Cl⁻. Furthermore, tail currents, measured following activating voltage steps, using SO_4^{2-}-filled electrodes (without loading the cell with Cl⁻), reverse in polarity at −60 mV (Fig. 2*c*), which corresponds well with E_{Cl} in these cells[20]. E_{rev} averaged −1.7 mV (s.e.m. = 3.5 mV, $n = 20$ from 7 cells) when Cl⁻-filled electrodes were used and −44 mV (s.e.m. = 2.3 mV, $n = 9$ from 8 cells) when SO_4^{2-}-filled electrodes were used. These findings taken together are consistent with the hypothesis that the conductance involves primarily, if not exclusively, Cl⁻.

Ca-dependent Cl⁻ conductance mechanisms have been reported in toad oocyte[21] and salamander photoreceptor membranes[22] but their functional roles in these cells are unclear. Ca-dependent depolarizing shifts have also been observed in vasopressinergic neurones cultured from the mammalian hypothalamus[1]. In our experiments, it was necessary to eliminate some of the K^+ conductances in order to reveal the Ca-dependent Cl^- conductance. Activation of K^+ conductances attenuates spread of depolarizing current injections, indicating that the Cl^- conductance may be electrotonically distant from the current-passing microelectrode. Presumably, membrane depolarization increases intracellular Ca^{2+} concentration, $[Ca^{2+}]_i$, by activating Ca^{2+} conductances in plasma (and/or cisternal) membranes. It is well established that Ca^{2+} conductances are present at terminals in the vertebrate central nervous system, where they participate in transmitter release. If the Ca-dependent Cl^- conductance is also present at nerve endings, and provided that E_{Cl} is similar at terminals and cell bodies[20], then activation of the conductance at this level, by depolarization and/or Ca^{2+} entry, may serve to repolarize the terminal region, thus limiting transmitter release.

We thank Joann Mazzetta for culturing spinal cord neurones, Drs Amy MacDermott and David Lange for helpful criticism and Mary Ann Bragg for typing the manuscript.

The agonist effect of dihydropyridines on Ca channels

A. M. Brown, D. L. Kunze & A. Yatani

Department of Physiology and Biophysics, University of Texas
Medical Branch, Galveston, Texas 77550, USA

Dihydropyridines (DHP) have great potential for clinical use because of their inotropic and vasomotor effects. The mechanism of action is unknown although Ca currents have been implicated[1,2]. Here we report measurements of single channel and whole cell cardiac Ca currents after application of two DHP agonists BAY K 8644 and CGP 28 392. Whole cell Ca currents from individual myocytes were increased and the 50% effective doses (ED_{50}) were similar to those reported for contractility in rabbit aorta and guinea pig heart[1] and catecholamine release from cat adrenal glands[3]. The measured ED_{50} was also consistent with the apparent dissociation constant (K_d) of a high affinity binding site present in cardiac sarcolemmal vesicles[4–7]. We propose that the molecular basis for these results is an increase in the probability that a single Ca channel, having opened and closed, will subsequently re-open during membrane depolarization. At high concentrations of BAY K 8644 and in the presence of 96 mM Ba, different effects are observed, primarily a marked prolongation of open time[8].

Neonatal rat and adult guinea pig ventricular cells were prepared using the methods of refs 9 and 10 respectively. The guinea pigs (300–500 g in weight) were anaesthetized with pentobarbital (50 mg per kg body weight)) and the ascending aorta was cannulated *in situ* under artificial respiration before removing the heart[11]. The enzyme solution used for dispersion was washed out with 'power soup'[12].

Whole cell currents were recorded using the blown-out patch clamp method[13] and single channel Ca currents were recorded using the patch gigaseal method in the cell-attached configuration[13]. Cardiac action potentials were recorded in five experiments with standard intracellular microelectrodes. For whole cell Ca currents, the extracellular fluid (in mM) was: NaCl 135, KCl 5.4, $CaCl_2$ 1.8, $MgCl_2$ 1.0, glucose 10, HEPES 5.0 (*p*H was adjusted to 7.4 with NaOH). The intracellular pipette contained (in mM), KOH 110, aspartic acid 110, KCl 20, HEPES 5, EGTA 0.2, ATP 2 and the *p*H was adjusted to 7.3 with KOH. The Ca patch pipette contained (in mM): $CaCl_2$ 40, tetraethylammonium chloride (TEACl) 20, KCl 5.5, glucose 20, 4-aminopyridine (4-AP) 5.0, Tris-HCl 55. The *p*H was adjusted to 7.4 with KOH. The Ba patch pipette contained (in mM): $BaCl_2$ 96, HEPES 10 (*p*H 7.4). All experiments were done at room temperature (20–22 °C).

Both agonists at low concentrations produced dose-dependent increases in the duration of the ventricular action potential with no changes in the resting potential (Fig. 1*D*). At an action potential of 0 mV, the duration was increased by as much as 25% whereas at half-peak amplitude the duration was increased by a factor of two or more. The effects occurred within 1 min and were usually complete within 5 min (Fig. 1*E*). The effects of the agonists were reversible after 15–20 min of washing. The effect of BAY K 8644 (10^{-7} M) on whole cell peak Ca currents was an increase between −20 and +30 mV (Fig. 2*A*) and similar values were obtained when Cs was substituted for K in the

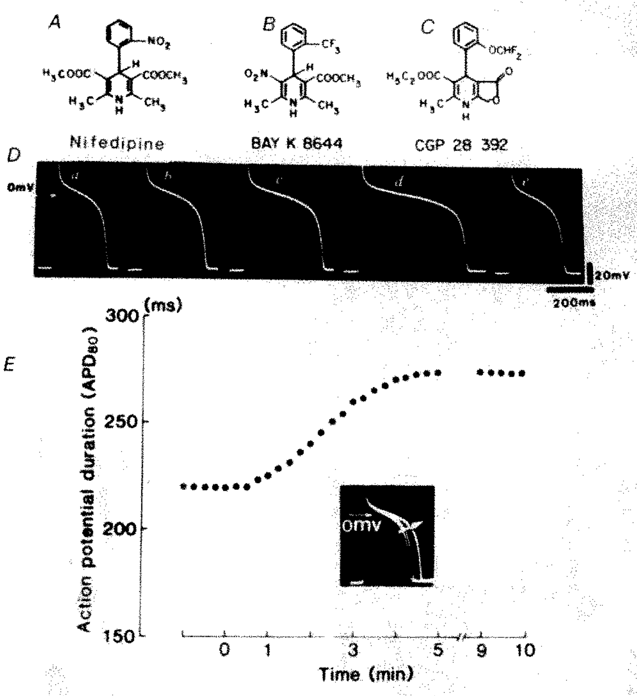

Fig. 1 *A–C*, Chemical structures of nifedipine, BAY K 8644 and CGP 28 392. The difference between dihydropyridines with antagonist effects and those with agonist effects is that the former have two freely rotating ester groups whereas the latter have only one. The difference between BAY and CGP is that a nitro group replaces an ester group in BAY and one ester group is locked into a rigid ring structure in CGP. *D*, *E*, The effects of BAY on the action potential (AP) of single isolated adult guinea pig ventricular cells. *D*, Dose-dependent changes; *a*, control; *b*, 5×10^{-9} M; *c*, 5×10^{-8} M; *d*, 5×10^{-7} M and *e*, recovery 15 min after washing. The major effect is a prolongation of AP duration. *E*, The time course of the changes in AP measured at 80% repolarization (APD_{80}) produced by 5×10^{-9} M BAY. The inset shows the AP before and 1, 3, 5 and 10 min after adding the drug. Stimulation occurred every 15 s.

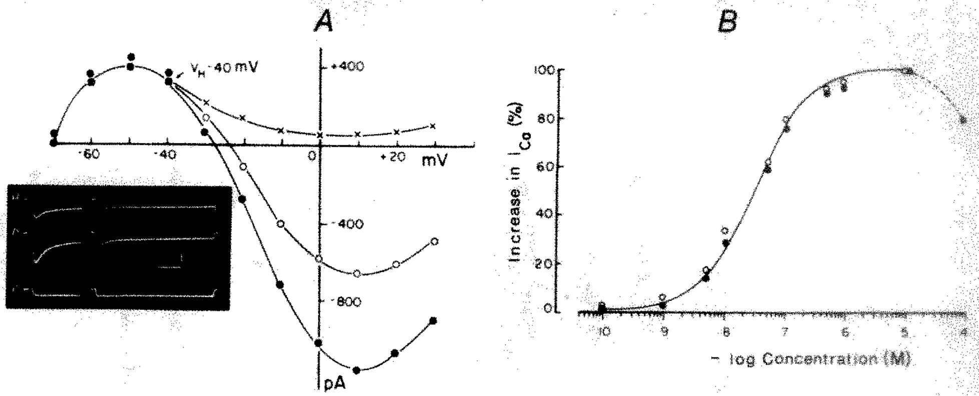

Fig. 2 *A*, Effects of BAY K 8644 (10^{-7} M) on Ca current and peak *I–V* curve of single adult guinea pig ventricular myocytes. ○, Control; ●, plus BAY K 8644 (10^{-7} M); X, plus Co. The holding potential (V_H) was −40 mV and steps were applied every 10 s. The inset shows the currents in response to steps from −40 to +10 mV before and after drug (*a*, *b*) and after blocking calcium current with 3 mM Co (*c*). There are two time bases, left, 10 ms; right, 100 ms. Current calibration was 500 pA. The outward holding current is produced by using a holding potential which is less negative than the zero current potential; it is carried by the inward rectifier. Ca currents for the dose–response curves were measured as the difference in inward current before and after addition of Co. *B*, Dose–response curves of maximum Ca current in adult guinea pig for the CGP agonist (○) and the BAY agonist (●). Each point is the mean value of seven cells for BAY and five cells for CGP. S.E. values were $< \pm 10\%$ for both agents. The solid line extends only to the peak I_{Ca} and is the theoretical curve for one to one agonist–receptor interactions. ED_{50} is 3×10^{-8} M. Similar results were obtained in neonatal rat myocytes. The maximum increase produced by BAY was three- to fourfold whereas that produced by CGP was twofold.

intracellular pipette. At doses of 10^{-7} M or greater, the effects for BAY K 8644 but not CGP 28 392 appeared to be larger at negative test potentials. Inactivation from the peak was quicker, the steady current was larger and tail currents were prolonged. As results of this kind have been attributed to loss of potential control[14], we investigated these effects using neonatal myocytes, which have smaller currents and simpler geometry due to the absence of T-tubules[15]. The bath solution (in mM) was: $CaCl_2$ 5, TEACl 20, KCl 5.5, 4-AP 5, Tris-HCl 90, glucose 20; *p*H was adjusted to 7.3 with KOH. The pipette solution (in mM) was: CsOH 110, aspartic acid 110, CsCl 20, HEPES 5, EGTA 1, ATP 2; *p*H was adjusted to 7.3 with CsOH. The currents were controlled in these cells and in these conditions, a voltage-dependence of drug action was not observed. Nevertheless we cannot exclude a voltage-dependent effect in adult cells. The effects of alteration in the state of the channel were investigated in inactivated and rested channels. To study steady-state inactivation, holding potentials as negative as −70 mV were required. This could reactivate Na currents which were abolished at the usual holding potential of −40 mV. To avoid this, tetrodotoxin (TTX) was added in doses of 5×10^{-5} M to completely block Na currents[16]. Steady-state inactivation measured using prepulses of several seconds duration combined with test pulses to either +10 or −10 mV was unaffected by agonists. We did not observe the blocking action reported for syncytial cardiac Purkinje preparations[17] at the ED_{50} using holding or conditioning potentials of −40 mV.

The effects were specific for Ca currents. The inward rectifier current activated by hyperpolarizing potentials to −100 mV and the outward currents activated at potentials above +20 mV were unaffected. The *β*-blocker propranolol at a concentration of 5×10^{-6} M had no effect; thus *β*-receptors which when activated by noradrenaline also increase Ca currents in these cells[18,19] were not involved. The Ca currents were eliminated by the specific DHP Ca antagonist nitrendipine in doses of 10^{-5} M or by substitution of Co for Ca extracellularly. The dose–response curves for both agonists were similar (Fig. 2*B*). At lower doses the effects were reversible; at higher doses recovery was partial. This may be partially due to the fact that Ca currents in small cells run down with time[20,21]. A maximum effect at an agonist concentration of 10^{-5} M was also observed when contraction of aortic smooth muscle or heart[1] or noradrenaline release[3] was used as the observable response.

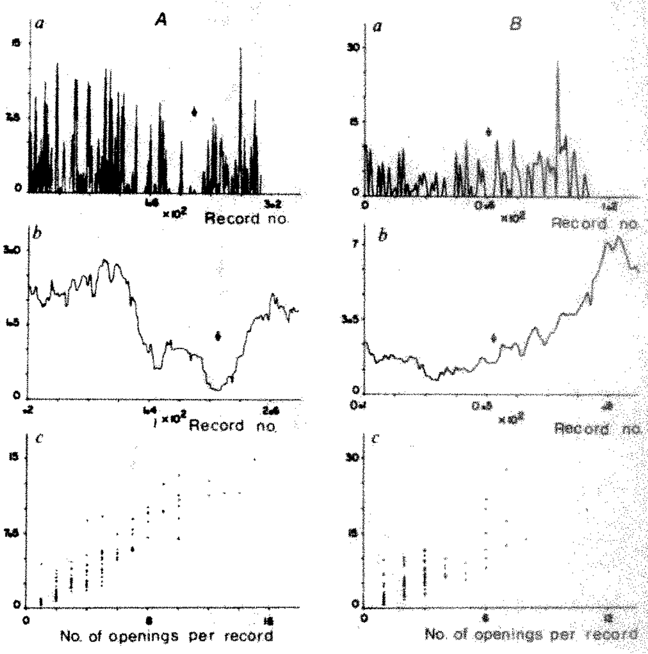

Fig. 3 Single channel activity from two cell-attached patches on neonatal rat ventricular myocytes during control and after addition (marked by arrows) of BAY K 8664 (*A*) and CGP 28 392 (*B*) in doses of 5×10^{-7} M. The patch pipette contained 40 mM Ca. In *B*, the potential step was applied at 0.25 Hz for 70 ms. Resting potential, V_R, estimated (from whole cell mesurements) was −50 mV. The patch potential was −20 mV, and the step potential (V_{step}) was +50 mV. In *A* the step was 100 ms in duration, holding potential was −20 mV, and V_{step} was 40 mV; repetition rate was 0.2 Hz. Records were low pass filtered at 1 kHz using a zero phase, nonringing, digital filter; sampling rate was 50 μs per point. *a*, Percentage of open time against the record number. *b*, Smoothed versions of *a*, where smoothing is done by averaging at each point the surrounding 41 and 21 points in *A* and *B* respectively. Note that in *B*, rundown during control was small whereas in *A* it was substantial. *C*, The relationship between the percentage of open time (ordinate) and number of openings per record (abscissa). The data were fitted by linear regressions with $r = 0.84$ and 0.69, respectively. The slopes correspond to open times per opening of 0.88 and 1.0 ms in *A* and *B* respectively. Large deviations due to prolonged openings are not present.

To examine the mechanism of action at a molecular level, we studied single Ca channels. The trials consisted of up to 500 identical voltage steps 50–500 ms duration delivered at intervals of 4–12 s. Long periods of recording during control were associated with a progressive loss of activity and it was useful to construct a trace by trace 'diary' of the single channel activity. The diary consisted of measurements of the percentage of open time per record and the number of openings per record (Fig. 3). Figure 3 shows that in control experiments the activity was cyclic; it also confirms the occurrence of rundown. Addition of agonist was always associated with a large increase in activity although the cyclical pattern persisted. Similar results were observed in three additional experiments. At an agonist

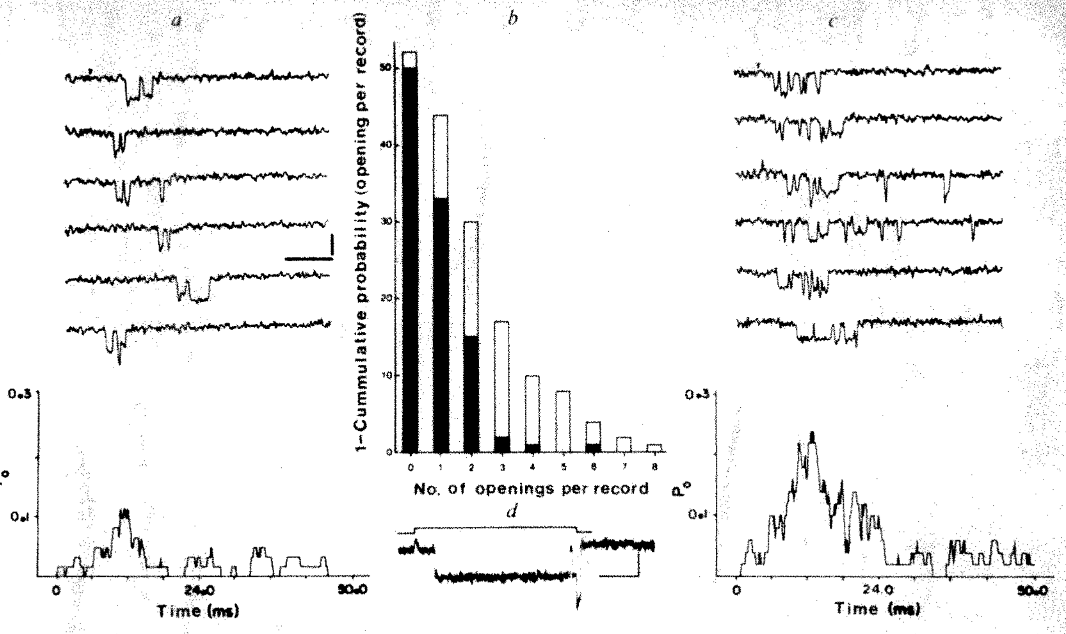

Fig. 4 Effects of agonist CGP 28 392 on single channel Ca currents (*a*, control; *c*, after drug). Control traces are representative of record numbers 25-65 and traces after drug are representatives of record numbers 80-120 shown in Fig. 3*B*. Arrows indicate onset of potential step. There were two channels in this patch (sixth trace in *a*, third trace in *c*). Bars are 0.4 pA and 15 ms. Linear components of capacitance and leakage have been subtracted. *c* was taken 3 min after addition of 5×10^{-7} M CGP 28 392 to the bath. Below *a* and *c* are the averaged currents for the record numbers referred to above—P_0 is the opening probability. *b*, Agonist effect on the distributions of openings per trace. ■, Control; □, plus CGP 28 392 (5×10^{-7} M). The ordinate is 1− the cumulative discrete probability density function of the number of openings per record. *d*, Effect on a single channel of 10^{-5} M BAY. Pipette contained isotonic Ba. V_H was the resting potential of −50 mV, V_{step}, +40 mV, pulse duration 100 ms. Calibration, 1 pA and 20 ms. Slope conductance calculated from the closure following return of the voltage step was 30 pS, which is about 20% greater than the usual value in isotonic Ba (ref. 18).

concentration of 5×10^{-7} M with 40 mM Ca in the patch pipette, the relationship between percentage of open time and number of openings per record was monotonic and highly correlated. In 1,536 events there was no evidence of greatly prolonged open times such as those observed in Fig. 4*d*. Unitary amplitudes were unchanged and the major effect was an increase in the average number of openings per sample due to the fact that re-openings became more frequent (Fig. 4). When the individual single channel records were summed and averaged, they increased and decreased in the same way as the whole cell currents, and the increase due to agonist was consistent with the increase observed in whole cell current recordings (Fig. 4). The open time distributions were fitted by a single exponential function and were unaffected by agonist. The mean value of open time was 1.36 ± 0.76 ms ($n=815$) for the control experiments and 1.47 ± 0.98 ms ($n=721$) for agonist when holding potential (V_H) = resting potential (V_R) −20 to −40 mV and the voltage step (V_{step}) was +30 to +60 mV.

The mean values for waiting times (latencies to first opening) were unchanged. The openings occurred in bursts as already reported[20,22-24], and these gave rise to short and long closed times. The burst duration and gaps within bursts were unaffected and the mean closed times were also unchanged. Although increased re-opening should reduce the mean closed times, for pulsed data, the last closed times were not determined. More of the longer closed times are discarded in the control experiment so that the drug effect is obscured. When high agonist concentrations (10^{-5} M) were used with 96 mM Ba in the patch pipette, repetitive activity was markedly intensified and greatly prolonged openings appeared[8] (Fig. 4*d*). These events gave a bimodal distribution to the plots of percentage open time versus number of openings per record.

Bath applications of nitrendipine in doses which blocked the whole cell current responses also blocked the single channel responses. It is not surprising that DHPs gain access to the membrane patch via extra-patch membrane as these agents are highly lipophilic. However, it is not known whether equilibrium conditions for drug distribution are attained in the patch.

The effects on single channels were due to an increase in the probability of re-opening. We cannot exclude an increase in the number of activatable Ca channels, but the results suggest that much of the increase in whole cell current is attributable to the increased probability of re-opening. Two possibilities are that progression to an absorbing inactivated state was inhibited or that re-opening from a closed state was enhanced. The absence of an effect on steady-state inactivation might favour the latter interpretation. The concentrations we used indicate that the effects were mediated by the high-affinity binding sites. In these circumstances the agonists did not change channel structure sufficiently to increase unit conductance or duration in the open state. The dramatic changes observed at 10^{-5} M concentrations of agonist[8] indicate a considerable change in channel structure and might be mediated by the low-affinity binding sites described for these agents[4,6]. They might also be associated with the falling phase of the dose-response curves.

We thank Dr A. Scriabine (Miles Laboratories) and Dr G. Weiss (Ciba-Geigy) for supplies of the agonists. This work was supported in part by NIH grants NS 11453 and HL 25145.

Acetylcholine receptors of fish electric organs and mammalian skeletal muscle comprise four structurally homologous glycoprotein subunits in the mole ratio $\alpha_2\beta\gamma\delta$ (refs 1–4). All four subunits have leader sequences and are exposed on both sides of the membrane[5,6]. From amino acid sequencing, three groups[5,7,8] have predicted that each subunit has four hydrophobic α-helical transmembranous domains. Because the N-terminus of each subunit is thought to remain on the extracellular surface after cleavage of the leader sequence, this model predicts that the N- and C-termini are both on the extracellular side. An alternative model proposed by two other groups[9,10] predicts that there is, in addition, a fifth amphipathic transmembranous domain which would place the C-terminus on the cytoplasmic side. Here, using anti-subunit sera and monoclonal antibodies and their reaction with synthetic subunit peptides, we demonstrate that the C-terminus is in fact on the cytoplasmic surface. We also show that, contrary to other predictions[11], the most hydrophilic sequence on the extracellular domain of α-subunits is not the main immunogenic region.

More than half of the antibodies made against native acetylcholine receptors (AChR) are directed at a small part of the extracellular surface of the α-subunits called the main immunogenic region (MIR)[12–14]. It has been reported that the most hydrophilic part of an amino acid sequence is usually a prominent antigenic determinant[15]. Therefore, it has been suggested that the most hydrophilic sequence on the predicted extracellular domain of α-subunits would form the main immunogenic region, although we show here that this is not correct.

Peptides were synthesized corresponding to the N- and C-terminal 10 amino acids of each subunit (except for δ, where the C-terminal peptide extended from C-3 to C-12 because of synthetic difficulties with the penultimate cysteine) and to the predicted main immunogenic region on the α-subunit (residues 159–169; ref. 11) (Bachem). At the unnatural terminus of each peptide, a tyrosine was added so that the peptides could be labelled with ^{125}I.

Anti-receptor monoclonal antibodies from our library (refs 12–14 and unpublished data) and antisera to native receptor from *Torpedo californica* and its purified denatured subunits were tested for reaction with these ^{125}I-labelled synthetic peptides (see Table 1). The results indicate that the N-termini of the chains are negligible immunogens in the intact receptor. Antisera to SDS-denatured receptor subunits also showed negligible reactions with the N-termini, however, the C-termini of the β-, γ- and, to some extent, δ-subunits were significantly immunogenic. Comparison of the titres of these anti-subunit sera to intact receptor (all $\sim 2.5\ \mu$M) with their titres against C-terminal peptides suggests that ~20% of antibodies to β-subunits, ~6% of antibodies to γ-subunits, and ~0.4% of the antibodies to δ-subunits are directed at the C-terminus. Titres against intact receptor were measured by indirect immune precipitation in units of mol α-bungarotoxin binding sites bound per litre of solution, and converted to approximate molar concentration of antibody by assuming that all of the receptors were present as dimers (containing four binding sites) and dividing the titre by four. Titres against peptides were measured by indirect immune precipitation in units of mol peptide bound per litre of solution, and converted to approximate molar concentration of antibody by assuming that peptides were bound to both of the antibody binding sites and dividing the titre by two. The fraction of antibodies to the C-terminus was calculated by dividing the concentration of antibodies to the peptide by the concentration of antibodies to the intact receptor. Three monoclonal antibodies to β-subunits were found which recognized the C-terminus. These monoclonal antibodies were initially selected by S. Tzartos *et al.* and were used in refs 16–18. They are the result of the fusion of spleen cells from rats immunized with β-subunits with the mouse myeloma S194 as previously described[12–14]. Their subclasses are 163-IgM, 170-IgG2a and 172-IgG1.

Antibodies which bound to C-termini were tested to determine whether they bound to the extracellular surface or the cytoplasmic surface of the receptor. Receptor-rich membrane vesicles from *Torpedo* electric organ are sealed rightside-out[19], but can be permeabilized using saponin or lithium diiodosalicylate (LIS)[20]. The ability of native or permeabilized vesicles to adsorb antibodies to the C-termini was tested (Fig. 1, Table 2). These results clearly demonstrate that the C-termini of β-, γ- and δ-subunits are on the cytoplasmic surface of the receptor and are accessible to antibody binding only when receptor-rich membrane vesicles have been permeabilized to permit entry of the antibody molecules. Pretreatment of the vesicles with saponin (0.3% or 3%) also permitted the vesicles to adsorb antibodies to the C-termini (Fig. 1). Previously, we found 11 monoclonal antibodies to receptor which required saponin to bind to receptors in the postsynaptic membrane of muscle and then showed

mAb 172				0	182				
10 Anti-γ antibodies						0	0		
20 Anti-δ antibodies								0	0

Peptides were labelled with ^{125}I to specific activities of about 3×10^{18} c.p.m. mol^{-1} by the same basic procedure reported for labelling α-bungarotoxin[30]. After dilution to 1×10^{-9} M (in 0.5% Triton X-100, 100 mM NaCl, 10 mM NaN_3, 10 mM Na phosphate buffer *p*H 7.5), triplicate 1-ml aliquots were incubated overnight with 5 µl of antisera or 2 µl of monoclonal antibody plus 3 µl of normal rat serum. After precipitation with goat anti-rat IgG, the washed pellets were counted. Normal rat serum was used as a blank. MIR, main immunogenic region.

Table 2 Inhibition of antibody binding to C-terminal peptides by receptor in various forms

	% Inhibition of binding by 3×10^{-8} M AChR		
	Native vesicles	LIS-permeabilized vesicles	Soluble receptor
Anti-β serum	0	68	71
Anti-β mAb 163 (IgM)	3	11	31
Anti-β mAb 170 (IgG)	0	74	55
Anti-β mAb 172 (IgG)	0	52	59
Anti-γ serum	0	39	45
Anti-δ serum	0	44	85

Inhibition experiments were conducted as described for Fig. 1.

by electron microscopy using colloidal gold-labelled anti-antibody that in every case the antibodies bound to the cytoplasmic surface of the membrane[16]. Saponin treatment was less effective than LIS treatment (Fig. 1). This observation can be explained[20] by the fact that saponin only makes holes in the membrane through which antibodies can enter the vesicle, whereas LIS not only disrupts the vesicle, but also removes a protein (molecular weight 43,000) which is known to associate with the cytoplasmic surface of β-subunits[21]. This observation further supports our proposal that antibodies to the C-termini of the subunits bind to the cytoplasmic surface of the receptor. To test this conclusion further, we prepared antisera against the C-terminal peptides of all four subunits and showed that LIS-extracted but not native receptor-rich vesicles could adsorb those antisera[22].

Our results conclusively demonstrate that models[4,7,8] which place the C-termini of receptor subunits on the extracellular surface of the postsynaptic membrane are incorrect. Those models[9,10] which propose a fifth amphipathic domain may be correct. R. Stroud and co-workers have reached a similar conclusion using electron microscopy to localize binding of antisera to the C-terminus of δ-subunits (personal communication). A fifth amphipathic transmembranous domain is especially appealing because it provides a hydrophilic surface for lining the cation channel through the receptor, which must have a hydrophilic surface to accommodate the high flow rate of hydrated cations known to occur through the channel[23].

It was proposed that the main immunogenic region of the receptor is formed by the most hydrophilic sequence of the α-subunits (amino acids 161-166)[11]. However, Table 1 shows that the synthetic peptide α 159-169 reacts only slightly with antisera to α-subunits and not at all with antisera to native receptor or with a collection of monoclonal antibodies to the main immunogenic region which react with denatured α-subunits. The main immunogenic region is a conformation-sensitive region—antibodies to it react better with native receptor than with SDS-denatured α-subunits. However, as these antibodies react with denatured α-subunits, they should bind to a synthetic peptide corresponding to the main immunogenic region. Therefore, the sequence α 159-169 does not form the main immunogenic region. Juillerat *et al.* recently reached a similar conclusion[24].

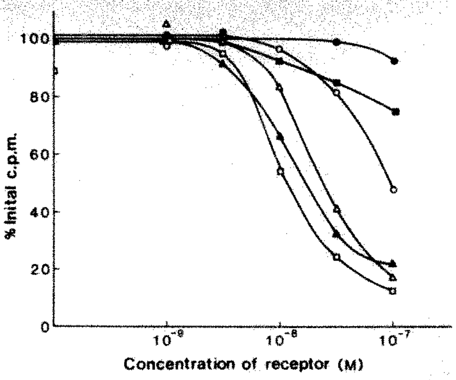

Fig. 1 Inhibition of binding of monoclonal antibody 172 to the ^{125}I- labelled C-terminal peptide of β-subunits. ●, Native vesicles; ■, native vesicles plus saponin; ○, *p*H 11 extracted vesicles; ▲, soluble receptor; △, *p*H 11 and Li diiodosalicylate (LIS)-extracted vesicles; □, denatured soluble receptor. Native receptor-rich membrane vesicles[19] were permeabilized with 0.3% saponin[16], or extracted with *p*H 11[29], or extracted first with *p*H 11 and then with 10 mM LIS[20]. Affinity-purified solubilized receptor[30] was denatured with 1% SDS and then diluted to 0.15% SDS in 0.5% Triton X-100. Triplicate 1-ml aliquots of ^{125}I-labelled C-terminal peptide at 1×10^{-10} M (in 100 mM NaCl, 10 mM NaN_3, 10 mM Na phosphate *p*H 7.5) were mixed with the indicated concentrations of receptor (measured as α-bungarotoxin binding sites[30]). Antibody was added overnight at a concentration of 2×10^{-10} M (measured as α-bungarotoxin binding sites precipitated per litre) in the presence of 5 μl of normal rat serum as carrier, then goat anti-rat IgG was added. The resulting pellet was washed and counted.

To test this conclusion further, a larger peptide from the same region of the α-subunit (amino acids 152-167) was synthesized and coupled to keyhole limpet haemocyanin by glutaraldehyde, for use as an immunogen. Spleen cells from an immunized rat were fused with S194 mouse myeloma cells as previously described[12,13,19] to produce a hybridoma secreting a monoclonal antibody designated mAb 236 (M.C. *et al.*, in preparation). This antibody bound to α-subunits but not to β-, γ- or δ-subunits

Table 3 Competition between monoclonal antibody to α 152-167 and monoclonal antibodies to MIR for binding to AChR in an ELISA

	Additivity index (raw data)			
	mAb 236	mAb 6	mAb 35	mAb 203
mAb 236 (anti-α 152-167)	(0.50 ± 0.04)	82 (0.80 ± 0.03)	96 (0.99 ± 0.08)	97 (1.34 ± 0.12)
mAb 6 (anti-*Torpedo* MIR)		(0.38 ± 0.04)	11 (0.51 ± 0.05)	−32 (0.42 ± 0.02)
mAb 35 (anti-eel MIR)			(0.53 ± 0.04)	−12 (0.61 ± 0.04)
mAb 203 (anti-human MIR)				(0.86 ± 0.06)

Receptor was bound to microtitre dishes (Immulon 1, Dynatech) by adding 50 μl per well of a 2×10^{-8} M solution in 0.01 M Na bicarbonate buffer, *p*H 9.5 overnight at 4 °C. Unreacted sites on the plates were quenched by adding 200 μl of 0.5% bovine serum albumin in 5% Tween 20 for 15 min. This was followed by four washes with the same solution. Monoclonal antibodies at concentrations chosen to just saturate this assay after overnight incubation at 4 °C, were added in the same solution. Monoclonal antibody binding was measured using a monoclonal antibody to rat IgG κ-chains (MAR 18.5) (ref. 26) coupled to glucose oxidase[27]. The raw data shown are the absorbance in the ELISA for each monoclonal antibody or combination of monoclonal antibodies corrected by subtracting the absorbance of blank wells. The additivity index (AI)[28] is calculated as follows: $AI = 100\ ((2A_{1+2}/A_1 + A_2) - 1)$ where A_1 is the absorbance with the first monoclonal antibody alone, A_2 is the absorbance with the second monoclonal antibody alone, and A_{1+2} is the absorbance with the two monoclonal antibodies together. A low value of the additivity index indicates that the two monoclonal antibodies cannot bind simultaneously and compete for binding, whereas a value near 100 indicates that both monoclonal antibodies can bind to receptor simultaneously and do not compete for binding. Combinations of monoclonal antibodies to the main immunogenic region (MIR) give low values of the additivity index. The absorbance in the ELISA of combinations of either mAb 6 or mAb 35 with mAb 203, is close to the absorbance of mAb 6 or mAb 35, probably because mAb 6 was made against receptor from *Torpedo* electric organ[12], and mAb 35 was made against receptor from *Electrophorus* electric organ[13], whereas mAb 203 was made against receptor from human muscle[14], thus monoclonal antibodies 6 and 35 have higher affinity for the *Torpedo* receptor which was used as the antigen in this assay. Combinations of mAb 6, 35 or 203 with mAb 236 raised to the synthetic peptide α 152-167 give absorbances approximating the sum of the absorbances of the monoclonal antibodies added individually, showing that monoclonal antibodies bound to the MIR do not impair binding of mAb 236 to α 152-167.

bound to enzyme-linked immunosorbent assay (ELISA) wells (data not shown). Similarly, this antibody bound to intact receptor by ELISA and this binding was inhibited by both the synthetic peptides α 159-169 and α 152-167. Using this system, we tested whether mAb 236 competed for binding to the receptor with antibodies to the main immunogenic region. Table 3 shows that monoclonal antibodies to the main immunogenic region compete with each other for binding to receptor, whereas mAb 236 and monoclonal antibodies to the main immunogenic region can bind to receptors simultaneously. This shows that not only is the sequence 161-166 not the main immunogenic region, it is not even immediately contiguous to this region.

The studies described here reveal that predicting protein structure from cDNA sequences (the method used to predict the two alternative models[4,7-10] investigated here) is difficult and that immunochemical techniques are a useful approach for testing the predictions of such studies. Further studies with anti-peptide antibodies and other methods will be required to refine models of subunit structure and to account for the conformation changes which have been detected during the maturation and assembly of receptor subunits[25].

Photoreceptor-specific degeneration caused by tunicamycin

Steven J. Fliesler, Laurence M. Rapp & Joe G. Hollyfield

Cullen Eye Institute, Baylor College of Medicine, Houston, Texas 77030, USA

The antibiotic tunicamycin inhibits the biosynthesis of *N*-acetylglucosaminylpyrophosphoryl polyisoprenol[1-3], a key intermediate in the formation of the asparagine-linked oligosaccharides of glycoproteins[4]. The effects of tunicamycin have been studied in various biological systems[5], primarily with the aim of elucidating the role of the carbohydrate moieties in the cellular function of glycoproteins[6]. Rhodopsin, the visual pigment of retinal rod photoreceptor cells, is a membrane glycoprotein which consists of a single polypeptide chain (opsin) to which a chromophoric prosthetic group (11-*cis*-retinaldehyde) and two asparagine-linked oligosaccharide chains are covalently attached[7]. The glycosylation of opsin can be blocked with tunicamycin *in vitro* in conditions where polypeptide synthesis is only slightly decreased[8,9]. We have reported[9] that tunicamycin can disrupt the normal assembly of rod outer segment membranes *in vitro* without significantly inhibiting the biosynthesis or intracellular transport of opsin. Here we report that intraocular injection of tunicamycin produces a photoreceptor-specific degeneration characterized by (1) progressive shortening of rod outer segment, (2) decreased electroretinogram amplitudes, (3) cessation of rod outer segment membrane assembly, and (4) eventual photoreceptor cell death.

Frogs (*Rana pipiens*, 20-25 g each) were maintained at 23°C under cyclic lighting (12 h light-12 h dark) in a metabolic incubator. In each animal, one eye was injected with 1.0 μg of tunicamycin (Calbiochem; in 10 μl dimethyl sulphoxide (DMSO)); the contralateral (control) eye was injected with 10 μl DMSO alone. At various times (1, 4, 8 and 20 days), animals were dark-adapted, immobilized, and electroretinogram (ERG) measurements were performed as described previously[10]. The light intensity necessary to obtain a criterion *b*-wave response of 30 μV was defined as the threshold (I_t, expressed in −log units). Following ERG measurements, animals were exposed to normal room illumination for 1 h and the eyes were then removed and processed for light microscopy[11].

No differences between the control and tunicamycin-injected eyes were observed with respect to maximal *b*-wave amplitude one day after injections (Fig. 1*a*,*b*). However, a small increase in threshold was observed in tunicamycin-injected eyes relative to controls: $\Delta I_t = 0.6$ (Fig. 1*a*,*b*). By day 4, a tunicamycin-induced decrease in maximal *b*-wave amplitude to 73.6% of control (Fig. 1*d*) and increase in threshold, $\Delta I_t = 1.6$ (Fig. 1*c*,*d*) were clearly evident. Further decreases in the maximal *b*-wave amplitude to 31.6% of control (Fig. 1*f*) and increases in threshold to $\Delta I_t = 3.4$ (Fig. 1*e*, *f*) were observed by day 8. During the time course of the decrease in maximal *b*-wave amplitude, the ERG *a*-wave amplitude also declined progressively. Finally, no ERG responses could be elicited from eyes 20 days after the tunicamycin injection (Fig. 1*h*), in contrast to control eyes (Fig. 1*g*). Linear regression analyses of ERG amplitudes as a function of post-injection time indicated that the decrease in maximal *a*-wave and *b*-wave amplitudes occurred at a rate of approximately 5% per day (correlation coefficient, 0.98), relative to controls.

The extent of retinal degeneration induced by tunicamycin was assessed by light microscopy. One day after the tunicamycin injection, no gross morphological changes were apparent relative to contralateral controls (Figs 2*a*, 3). However, by 4 days post-injection (Figs 2*b*, 3), rod outer segments in tunicamycin eyes (29.1 ± 3.7 μm) were reduced in length by nearly 23% ($P < 0.05$, $n = 3$) relative to those of controls (37.9 ± 5.5 μm). Furthermore, retinal pigment epithelium cells in the tunicamycin-injected eyes were laden with phagosomal debris (arrows in Fig. 2*b*). Eight days after the tunicamycin injection, photoreceptor degeneration had progressed markedly (Figs 2*c*, 3). Rod outer segments in the tunicamycin-injected eyes (21.8 ± 1.1 μm) were shortened to 48% of control length ($P < 0.001$, $n = 3$). The retinal pigment epithelium cells exhibited several pathological features, including hypertrophy and rounding, clustering of pigment granules in the apical cytoplasm, retraction of apical

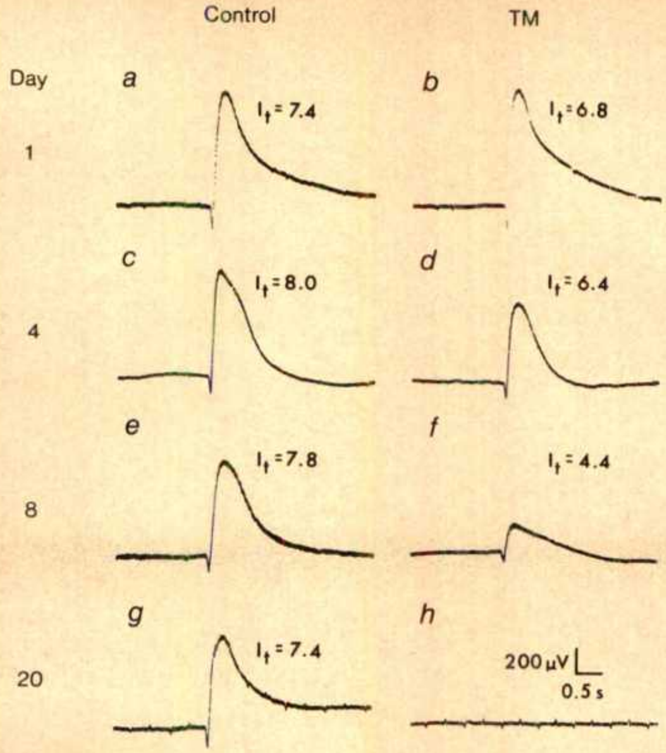

Fig. 1 Electroretinogram (ERG) recordings obtained following intraocular injection of frogs with DMSO (control: *a*, *c*, *e*, *g*) or tunicamycin (TM: *b*, *d*, *f*, *h*).

Methods: Groups of frogs (3 per time point) were anaesthetized by immersion in 0.5% MS-222 (Sigma) and injected in one eye with a tunicamycin solution (1 μg, in 10 μl DMSO) and in the contralateral eye with DMSO (10 μl). Injections (in the vitreous, at the pars plana) were performed under a dissecting microscope, using a Hamilton syringe fitted with a 32-gauge needle. Dark adaptation, immobilization by injection with curare and isoproteranol, and ERG measurements were perfomed as described previously[10]. Data from the experimental and control eyes are shown for a single animal representative of the group at the given post-injection time. Threshold values (I_t, in −log units) are given in each panel.

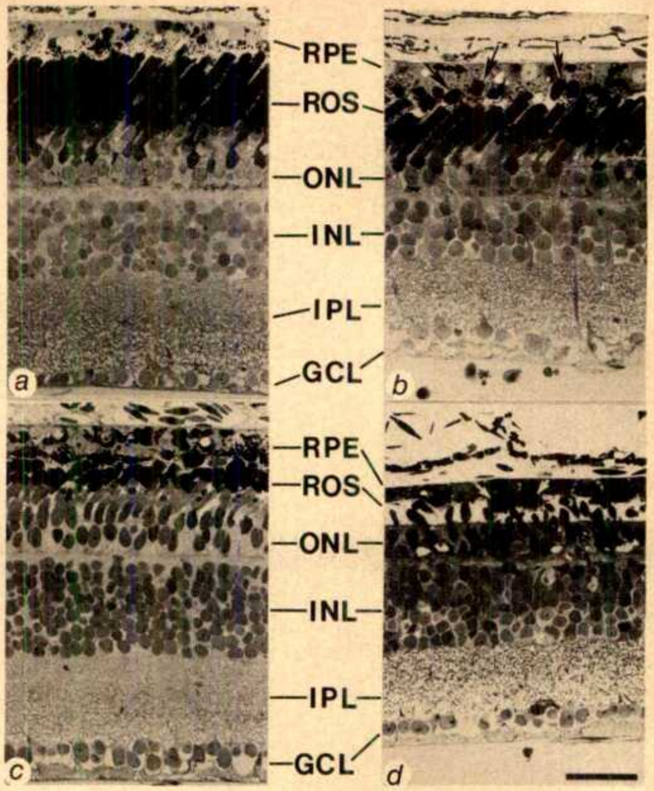

Fig. 2 Light micrographs of retinas from tunicamycin-injected eyes. Frogs were killed at (*a*) 1, (*b*) 4, (*c*) 8 and (*d*) 20 days following intraocular injection of tunicamycin, ~1 h after initial exposure to light. Fixation and processing of tissue for light microscopy was carried out as described previously[11]. RPE, retinal pigment epithelium; ROS, rod outer segment; ONL, outer nuclear layer; INL, inner nuclear layer; IPL, inner plexiform layer; GCL, ganglion cell layer. Retinas from control eyes (not shown) exhibited morphology comparable to that shown in *a* at all post-injection times. Apparent differences in retinal cell layer thickness reflect normal regional variations and do not represent significant changes as a function of time following injection of tunicamycin (see Fig. 3*A*). Monocytes are present in the vitreous, proximal to the ganglion cell layer (*b*). Phagosomes (black arrows, *b*) of unusually large size and number are evident within the apical cytoplasm of retinal pigment epithelium cells. Migratory pigmented cells (white arrows, *d*) can be seen within the subretinal space; note the absence of rod outer segment debris in the subretinal space.

microvilli, and accumulation of densely staining cytoplasmic inclusions. At 20 days post-injection, the morphology of the retinal pigment epithelium and photoreceptor layer of the retina in the tunicamycin-injected eyes was highly degenerate (Figs 2*d*, 3). Although many of the remaining rods in the tunicamycin-injected eyes retained some outer segment material, the rod outer segments were disoriented and were reduced in length by 73% ($P < 0.001$, $n = 3$) relative to controls. The lack of accumulated rod outer segment debris in the subretinal space and the engorged appearance of the retinal pigment epithelium indicated that phagocytosis continued after the injection of tunicamycin.

Rod outer segments exhibited a progressive and significant decrease in length as a function of post-injection time, at a rate of about 4% per day (correlation coefficient, 0.97). Even during the most advanced stages of photoreceptor degeneration, there was no significant thinning of other retinal layers (Fig. 3*A*; $P > 0.3$, $n = 3$). However, there was a progressive and selective loss of photoreceptor cells with time, resulting in nearly a 30% decrease ($P < 0.02$, $n = 3$) in the density of nuclei in the outer nuclear layer by day 20, relative to controls (Fig. 3*B*). Also, we did not observe any preferential loss of rod versus cone photoreceptors, as indicated by a relatively constant rod/cone ratio at all post-injection times.

Light microscopic autoradiography was performed after systemic labelling of the animals with ^{3}H-leucine to determine the incorporation of radiolabelled proteins into rod outer segment membranes, as indicated by the formation of a band of silver grains over the base of the rod outer segments. The apical displacement of these bands was measured from the base of the rod outer segments as a function of time (Fig. 4). One day following intraocular injection, bands of silver grains were observed in retinas from both tunicamycin-injected and control eyes approximately 2.0 μm from the base of the rod outer segments. In control eyes the displacement of these bands towards the distal tips of the rod outer segments progressed linearly at a rate of 0.92 μm per day, in good agreement with previous determinations of rod outer segment renewal rates for this animal[12]. In contrast, no further rod outer segment band displacement was observed in autoradiograms of tunicamycin-injected eyes throughout the experimental time course. These results indicate that renewal of rod outer segment membranes ceased some time within the first 4 days after the tunicamycin injection.

The photoreceptor cells are the most distal to the vitreous with respect to the other retinal cell types, and thus it is possible that the tissue concentration of tunicamycin in the photoreceptor layer was lower than in the other retinal cell layers. Therefore, it is remarkable that the degenerative changes were restricted to the photoreceptor cells, while the effects of tunicamycin on other retinal neurones were apparently negligible. The selective effect of tunicamycin on the photoreceptor cells may be due to the fact that their oxidative metabolic rate is similar to that of neoplastic cells[13], which have been shown to be extremely sensi-

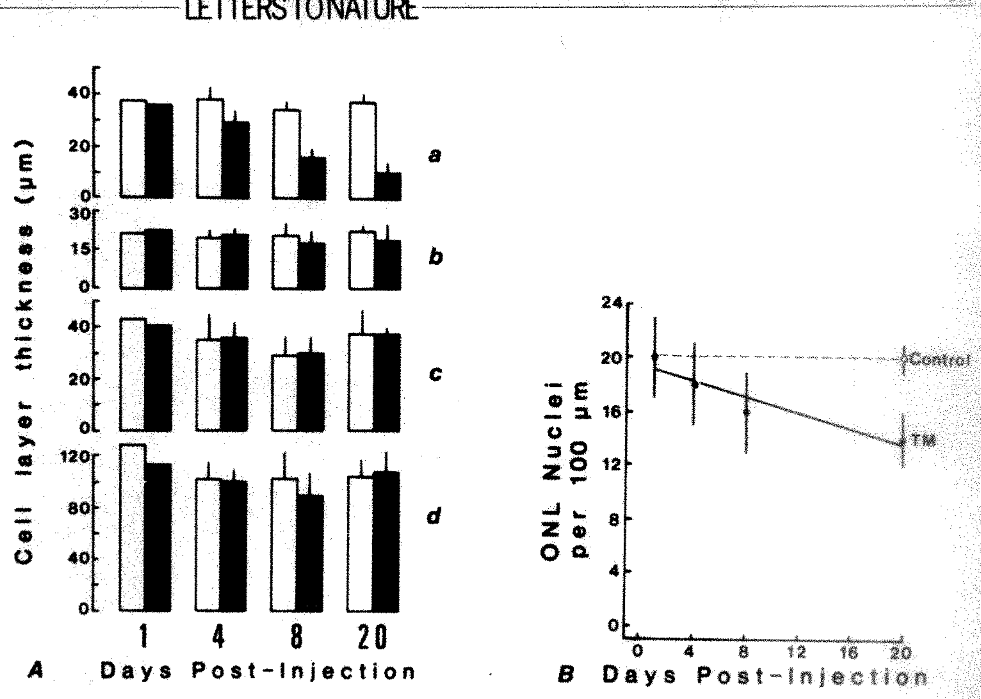

Fig. 3 Morphometric analysis of retinal cell layers as a function of time following intraocular injections with DMSO (control) or tunicamycin (TM). Measurements were made using a light microscope (×25 lens) coupled to a Zeiss Videoplan image analysis system via a video camera. Data represent the mean ±s.d. of 3 retinas for each condition; 5 random regions were analysed per retinal section and 15-20 individual measurements were performed per region. *A*, Length of rod outer segments (*a*) and thickness of the outer nuclear layer (*b*), inner nuclear layer (*c*), and the entire retinal expanse measured from the outer limiting membrane to the inner limiting membrane (*d*). Open bars, controls; shaded bars, TM. *B*, Quantitation of photoreceptor nuclei in the outer nuclear layer (ONL) (per 100 µm linear expanse) in tunicamycin-injected eyes (●) and controls (○). Linear regression analysis indicated the rate of photoreceptor cell loss to be about 1.6% per day (correlation coefficient, 0.90).

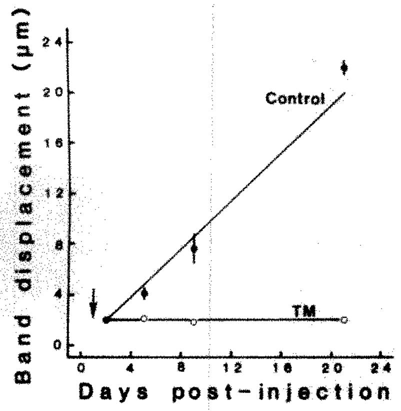

Fig. 4 Displacement of bands of silver grains in autoradiograms of rod outer segments as a function of post-injection time. **Methods:** Frogs were injected systemically with L-[4, 5-^{3}H] leucine (Amersham; 130 Ci mmol^{-1}; 10 µCi per g body weight) in the dorsal lymph sack. After 24 h (indicated by arrow), intraocular injection with DMSO (●) or tunicamycin (○) was performed (see Fig. 1 legend), permitting sufficient time for the assembly of several radiolabelled disk membranes in the basal portion of the rod outer segments before the introduction of the drug. At various times (2, 5, 9 and 21 days after ^{3}H-leucine injection), animals were killed approximately 1 h after initial exposure to light and the eyes were processed for light microscopic autoradiography[11]. Band displacement from the base of the rod outer segments was measured using a light microscope (×100 oil immersion lens) coupled to a Zeiss Videoplan image analysis system via a video camera. Quantitative analysis was performed as described in Fig. 2 legend. Linear regression analysis of the control (DMSO) points gave a slope of 0.92 µm per day (correlation coefficient, 1.00), corresponding to a daily renewal equivalent to 2.2% of the length of the rod outer segment.

tive to very low concentrations of tunicamycin[14]. In addition, the relative activity of the lipid-intermediate pathway for glycoprotein biosynthesis in the retina is greatest in the photoreceptor layer[15]. Therefore, tunicamycin might be expected to exert its inhibitory effects most prominently in the photoreceptor cells. Alternatively, the relative affinity of the uptake system for tunicamycin may be higher in photoreceptors than in other retinal cells.

These results are reminiscent of the kinds of pathological features observed in human rod–cone dystrophies, including retinitis pigmentosa[16–20]. A feature of these progressive blinding disorders is the selective deterioration of the photoreceptor cells, with the initial degeneration of the outer segments followed by pyknosis and cell death. The molecular etiology underlying these inherited retinal dystrophies remains unknown. These results suggest the novel possibility that a defect in the lipid-intermediate glycosylation pathway may be involved in one or more of these disorders. In this regard, we have recently obtained evidence which indicates grossly abnormal protein glycosylation in the rod photoreceptors of a human retina from a patient with an inherited chorioretinal degeneration resembling sectoral retinitis pigmentosa[21]. We are currently pursuing biochemical investigations to determine which retinal glycoproteins are affected during the tunicamycin-induced photoreceptor degeneration, as well as more detailed microscopic studies to assess potentially subtle ultrastructural changes which may occur in photoreceptors and other retinal cells during early times following intraocular injection of tunicamycin.

Recombinant vaccinia virus primes and stimulates influenza haemagglutinin-specific cytotoxic T cells

J. R. Bennink*, J. W. Yewdell*, G. L. Smith†, C. Moller* & B. Moss†

* The Wistar Institute, 36th Street at Spruce, Philadelphia, Pennsylvania 19104, USA

The ability of vaccinia virus to accept and express cloned genes[1–3] encoding immunologically important proteins of unrelated viruses[4–9] and malarial parasites[10] has suggested a novel approach to the development of live vaccines. Vaccinia virus recombinants retain infectivity and stimulate synthesis of specific antibodies to the cloned gene products in vaccinated animals. Moreover, animals inoculated with recombinants expressing the influenza virus haemagglutinin (HA)[7], the hepatitis B virus surface antigen[11], and type 1 herpesvirus glycoprotein D[8] were protected against subsequent challenge with the corresponding virus. For maximal effectiveness, vaccines should produce cellular as well as humoral immunity. We now report that a vaccinia virus recombinant, expressing the influenza HA, primes and stimulates a specific murine cytotoxic T-lymphocyte (CTL) response. Histocompatible cells infected with this recombinant also serve as targets for CTLs. These properties make vaccinia virus a unique tool for studying cell-mediated immunity and enhance the attractiveness of this vector for production of live vaccines.

The construction of the vaccinia virus recombinant H2-VAC (formerly referred to as vInf1) expressing the HA gene of influenza virus A/Jap/305/57 (H2N2) (JAP) has been described previously[7]. The HA gene was inserted next to a vaccinia virus transcriptional start site so that the authentic translational initiation and termination codons of the influenza gene were used. Tissue culture cells infected with the recombinant virus synthesized an HA polypeptide of the correct size that was glycosylated and transported to the cell surface[7,9]. The latter feature suggested that histocompatible cells infected with the recombinant virus might serve as targets for influenza virus-specific CTLs. To test this directly, P815 cells (a mastocytoma line derived from DBA/2 (*H-2*^{d}) mice) were infected and used as targets in a ^{51}Cr-release assay. CTLs derived from BALB/c (*H-2*^{d}) mice previously inoculated with JAP and restimulated with JAP-infected autologous splenocytes were able to lyse both JAP- and H2-VAC-infected cells (Fig. 1). In contrast, only background levels of cell lysis were observed using targets infected with wild-type vaccinia virus (Fig. 1). Control experiments verified that the latter were effectively lysed by CTLs prepared from vaccinia virus-infected mice (not shown). These results confirm our previous evidence that the HA is expressed on the surface of cells infected with recombinant vaccinia virus and further demonstrate that the HA can interact with class I major histocompatibility complex molecules in a manner sufficient for recognition by CTLs.

We next examined the ability of the recombinant vaccinia virus to restimulate *in vitro* splenocytes derived from BALB/c mice primed 3 weeks earlier by infection with JAP. Figure 2 shows that CTLs stimulated by H2-VAC were able to efficiently lyse cells infected with JAP or H2-VAC itself but not cells infected with an influenza B virus or wild-type vaccinia virus. As anticipated, we repeatedly found no detectable anti-influenza virus CTL activity when wild-type vaccinia virus was used for stimulation (not shown).

Further experiments demonstrated that the recombinant vaccinia virus could also prime for an influenza virus-specific CTL response. BALB/c mice were inoculated with recombinant or wild-type vaccinia virus; after 4 weeks, splenocytes were stimulated *in vitro* with JAP. Figure 3*a* shows that the recombinant virus was able to prime for an influenza virus-specific CTL response, whereas influenza virus-specific priming did not occur when mice were inoculated with wild-type vaccinia virus (Fig. 3*b*). Note that CTLs induced by H2-VAC priming and JAP secondary stimulation lysed cells infected with H2-VAC and

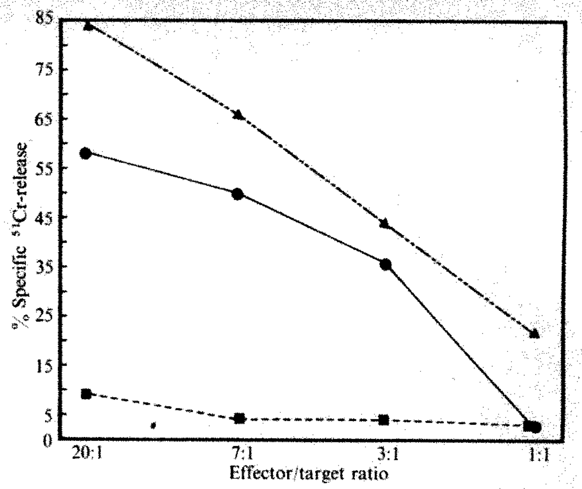

Fig. 1 Lysis of H2-VAC-infected target cells (–●–) by anti-influenza virus-specific CTLs. BALB/c splenocytes for *in vitro* stimulation were obtained from mice 2–4 weeks after intraperitoneal immunization with allantoic fluid containing 200 haemagglutinating units of JAP. Primed spleen cells (5×10^7) were cultured for 6 days in the presence of 2.5×10^7 autologous spleen cells infected with JAP at a multiplicity of 100 egg infectious doses (EID) per cell, then tested in a standard ^{51}Cr-release assay. P815 cells were infected with vaccinia virus WR isolate (- -■- -) or recombinant H2-VAC at a multiplicity of 10–100 plaque-forming units (PFU) per cell or with JAP (——▲——) at 10–100 EID per cell for 1 h[18]. After washing, cells were incubated for 6 h (JAP infection) or 15 h (vaccinia infection), then incubated for 1 h with ^{51}Cr at 37 °C, washed twice and dispensed into wells of microtitre plates (10^4 cells per well). Effector cells from *in vitro* cultures were added at various ratios, and after 4 h incubation at 37 °C, one-half of the culture supernatant was removed for determination of the concentration of released ^{51}Cr by γ counting. Per cent specific release was determined as follows: experimental release – spontaneous release (no CTLs) divided by total release (in the presence of detergent) – spontaneous release. Spontaneous release values were: JAP, 28%; H2-VAC, 14%; and wild-type vaccinia virus, 18%.

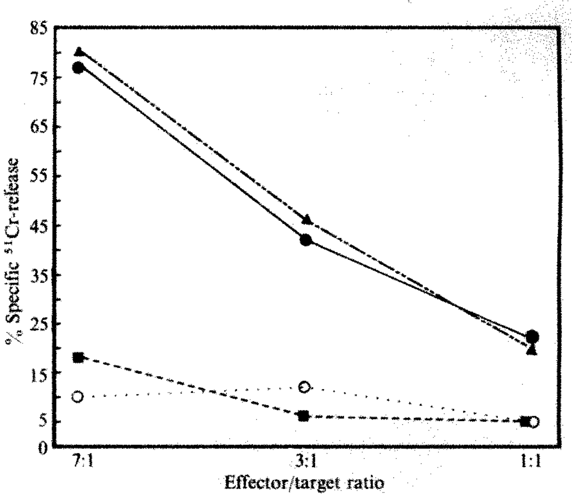

Fig. 2 Stimulation of JAP-primed CTLs by H2-VAC. Splenocytes from BALB/c mice primed with JAP were cultured for 6 days in the presence of BALB/c spleen cells infected with the recombinant H2-VAC virus (10 PFU per cell). ^{51}Cr-release assays were performed on P815 cells as described in Fig. 1 legend. Spontaneous release values were: JAP (——▲——), 18%; H2-VAC (-●-), 16%; wild-type vaccinia virus (--■--), 14%; and B/Lee (··○··), 39%.

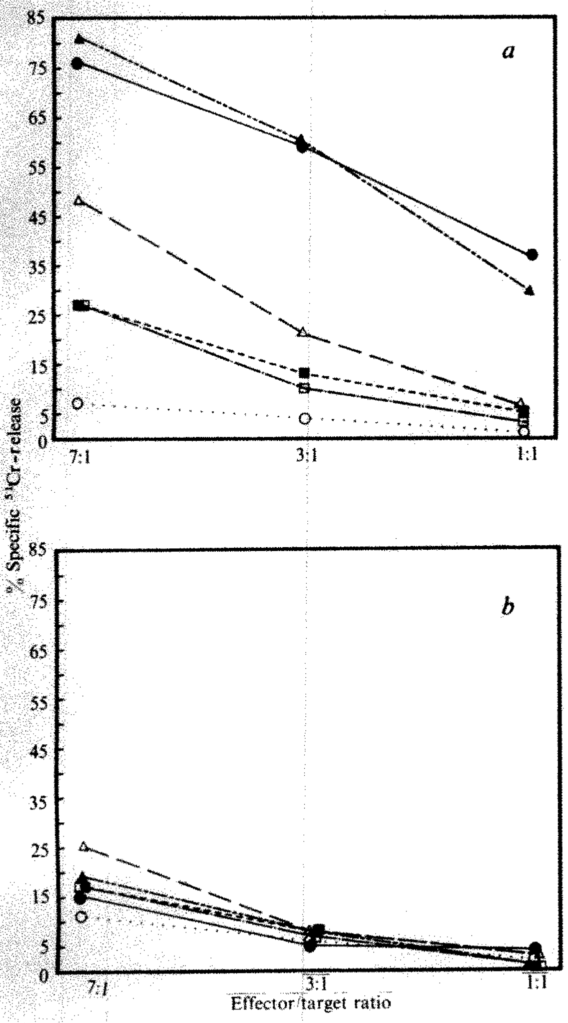

Fig. 3 *a*, *b*, Priming for an anti-JAP-specific CTL response by H2-VAC. Splenocytes were obtained from BALB/c mice 2–4 weeks after intravenous immunization with 10^7 PFU of the vaccinia recombinant H2-VAC (*a*) or the wild-type WR isolate of vaccinia virus (*b*). Primed splenocytes were restimulated *in vitro* with JAP-infected splenocytes. Target cells were prepared as described in Fig. 1 legend except that, after infection, all targets were incubated for 6 h before labelling with ^{51}Cr. Spontaneous release value for all targets was <13%. Targets: —●—, H2-VAC; - -■- -, wild type vaccinia virus; ——▲——, JAP; ··○··, B/Lee; —△—, PR8; —·□—·, HK.

JAP to a similar extent—this demonstrates that at least a significant proportion of these cells are specific for the HA. It is also apparent that cells infected with influenza A viruses of other subtypes [A/PR/8/34 (H1N1) (PR8) and A/HK/107/68 (H3N2) (HK)] were lysed at levels significantly greater than observed with B/Lee-infected cells. This could be due to cross-reactive recognition of heterosubtypic haemagglutinins by anti-JAP HA CTLs[12], in which case the better killing of PR8-infected cells could reflect the higher amino acid homology between JAP and PR8 haemagglutinins compared with JAP and HK haemagglutinins[13]. Alternatively, the observed cross-reactive lysis could be due to CTLs specific for other viral components whose *in vitro* stimulation depends on the presence of HA-specific T-helper cells primed by H2-VAC inoculation. In either case, it is important that priming for CTLs able to lyse cells infected with influenza viruses of H1N1 and H3N2 subtypes was not observed consistently between experiments; this, and the relatively small cross-reactive response, suggests that it may be due to stimulation of relatively infrequent T-cell clonotypes. Finally, as anticipated from the preceding experiments, virus priming and stimulation with H2-VAC alone resulted in the generation of JAP-specific CTLs (Fig. 4).

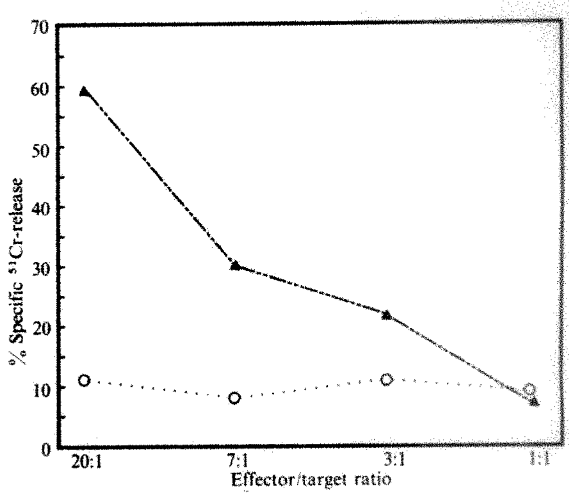

Fig. 4 Generation of anti-JAP-specific CTLs by priming and stimulation with H2-VAC. Splenocytes from BALB/c mice primed with H2-VAC were cultured for 6 days in the presence of BALB/c spleen cells infected with H2-VAC and tested for cytotoxic activity. Target cells were prepared as described in Fig. 1 legend. Spontaneous release values were: JAP (——▲——), 18%; B/Lee (··○··), 35%.

These data are of practical importance in two respects. First, we have shown that cells infected with a recombinant vaccinia virus can serve as excellent targets for CTLs specific for the product of the inserted gene. This, coupled with a wide host cell range, makes recombinant vaccinia virus an excellent tool for determining which viral antigens are recognized by CTLs, a question which remains unanswered for almost all viruses. The ability of vaccinia virus to accommodate large amounts of inserted DNA[14] means that it would even be possible to include multiple viral genes or viral and major histocompatibility complex genes in the same vaccinia virus vector. Second, regarding the potential use of recombinant vaccinia viruses as live vaccines, we have shown that these vaccines will probably efficiently prime recipients for secondary CTL responses. Although the role of CTLs in host defence against viral infection remains to be precisely defined[15], present evidence suggests that they reduce replication and dissemination of at least some viruses[16,17]. This property of recombinant vaccinia viruses may offer a significant advantage over subunit or inactivated vaccines, which do not, in general, prime for anti-viral CTL responses.

Transposition without duplication of infecting bacteriophage Mu DNA

Rasika M. Harshey

Research Institute of Scripps Clinic,
Department of Molecular Biology, 10666 North Torrey Pines Road,
La Jolla, California 92037, USA

Most models of DNA transposition invoke replication of the transposable element[1], but it is not clear whether a 'co-integrate' is an obligatory intermediate in the pathway leading to the production of simple insertions during transposition. Such an intermediate can be accounted for only by a replicative transposition scheme. Bacteriophage Mu is a temperate phage that can either lysogenize or lyse its host[2], and it encodes at least two modes of transposition as judged by the end-products generated by the process. During the lytic development of the integrated prophage, co-integrates are the predominant end-products[3]; transposition is coupled to replication during this phase[4]. A small number of simple insertions are also produced during the lytic growth[3], but during transposition from the infecting phage into the host chromosome, simple insertions are the main end-products[5]. Conditions can be found where the choice between the two kinds of end-products depends on a delicate balance between the essential transposition functions encoded by Mu[6]. Experiments[7,8] have suggested that the simple insertions which arise during transposition from the infecting phage may do so without Mu DNA replication. Here I demonstrate using an infecting phage with completely methylated DNA, a *dam*$^-$ (DNA adenine methylase) host and a combination of restriction enzymes that can cut either fully methylated or unmethylated DNA but not hemi-methylated DNA, that transposition of the phage DNA into the host chromosome does not involve a duplication of its DNA. This result may also have significance for other transposons[9] that do not appear to go through a co-integrate intermediate during transposition[10].

The *dam* gene of *Escherichia coli* codes for an enzyme that methylates the N-6 position of deoxyadenosine residues in DNA[11]. The methylated sequence, GATC, is cleaved by the restriction enzyme *Dpn*I. Another enzyme, *Mbo*I, cleaves the same sequence, but only if the sequence is unmethylated; however neither enzyme will cleave a hemi-methylated sequence[12]. I have used this property to design a strategy for investigating the state of replication of infecting Mu DNA, when it transposes into its host chromosome.

Phage [(Mu *cts* 62 445-5, *gin*$^-$(G+)][13] were methylated by growing them in a strain of *E. coli* containing the cloned *dam* gene (p *dam* 118)[14]. The DNA was digested with *Dpn*I (data not shown) to show that it was completely methylated. These phage were then used to infect a *dam*$^-$ *E. coli* host. At various times after infection, total *E. coli* DNA was isolated and checked for integration of Mu (Fig. 1*A*). Integration can be detected 8 min after infection (the exact time of detection of integration varies, being as early as 4 min in some experiments). Chromosomal DNA was then separated from unintegrated Mu DNA by non-equilibrium centrifugation on a sodium chloride gradient (Fig. 1*A*, lane *d*). Digestion of the integrated Mu DNA with *Hin*dIII showed that the two central *Hin*dIII fragments present in the phage DNA still remained, but the terminal *Hin*dIII fragments present in the phage DNA had disappeared, to be replaced by a smear, as would be expected from molecules that had transposed from the phage DNA into many different sites in the chromosome (Fig. 1*B*). The integrated DNA was also digested with *Eco*RI which releases larger terminal fragments. Again, only the central fragment could be detected (data not shown). Using these criteria, contamination from free phage DNA was judged to be <0.5%.

DNA isolated 8 min post-infection was digested with *Mbo*I and *Dpn*I respectively (Fig. 2*a*, *b*). Integrated Mu DNA is resistant to the action of *Mbo*I but completely digested by *Dpn*I, showing that no replication of the DNA had occurred during its transposition. However, this DNA is capable of further rounds of transposition as seen by the digestion pattern 15 min post-infection. Figure 2*c* shows that some of the integrated DNA is resistant to both *Mbo*I and *Dpn*I whereas some has become susceptible to *Mbo*I, indicating that a fraction of the integrated Mu DNA has gone through one round of replication (become hemi-methylated and hence resistant to both enzymes) and even two rounds (become unmethylated and hence sensitive to *Mbo*I). By 30 min post-infection, most of the integrated Mu

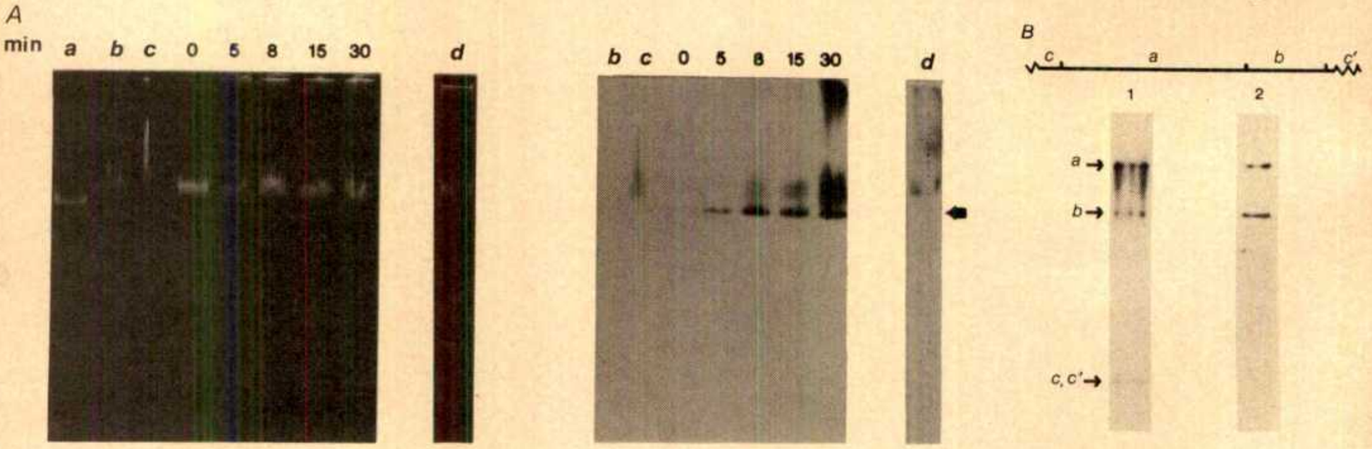

Fig. 1 Chromosomal integration of infecting Mu DNA. *A*, Total *E. coli* DNA (GM119) isolated at various times after phage infection was run on a 0.35% agarose gel, transferred to nitrocellulose and probed with radiolabelled Mu DNA. The left panel shows the ethidium-bromide stained fluorescence and the right panel the autoradiogram of the gel. Lane *a*, DNA isolated from phage; lane *b*, control *E. coli* DNA; lane *c*, DNA from a Mu lysogen. 0 to 30 indicate the time in minutes after infection at which total *E. coli* DNA was isolated. Lane *d*, DNA from the 8 min time point, separated from free phage DNA as described below. The arrow indicates the position of free phage DNA. *B*, Schematic diagram showing the distribution of *Hin*dIII sites in Mu 445-5. ~ represents heterogeneous host sequences. *a*, *b* Represent the internal fragments and *c* and *c'* the terminal fragments. *c* and *c'* are similar in size and band as a doublet. Lane 1, the *Hin*dIII digestion pattern of DNA from 445-5 phage, and lane 2 that from integrated Mu DNA 8 min post-infection.

Methods: Cells (GM119, *dam*, *dcm*-6) were grown to a cell density of 2×10^8 per ml at 37 °C. They were pelleted, resuspended on ice in buffer containing 20 mM Tris, 200 mM NaCl, 2 mM $CaCl_2$, 20 mM $MgCl_2$, *p*H 7.5. Phage were added at a multiplicity of infection (MOI) of 5, mixed gently for 1–2 min and diluted into pre-warmed broth at 37 °C. Cells were left shaking at 37 °C and at various times aliquots were withdrawn and total DNA isolated as described elsewhere[4]. Integrated Mu DNA was separated from the free phage DNA by running not more than 100 µg of total DNA over 10–30% NaCl gradients in 10 mM Tris, 1 mM EDTA *p*H 7.5, spun in a SW41 rotor, 25 °C, 37,000 r.p.m. for 3 h. High molecular weight DNA pelleted; it was recovered, redigested with pronase, re-extracted with phenol and precipitated with ethanol.

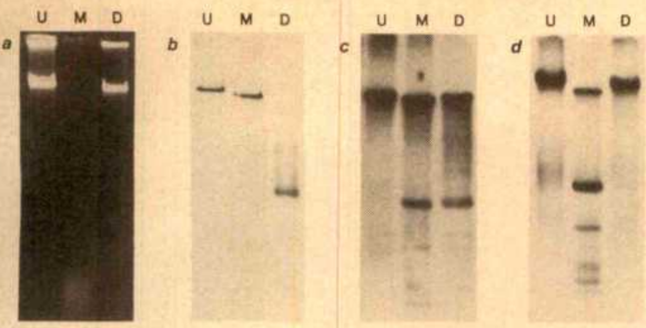

Fig. 2 *Mbo*I and *Dpn*I digestion pattern of integrated Mu DNA Agarose gels (0.5%) were run as in Fig. 1. *a*, Ethidium-bromide stained fluorescence of DNA 8 min post-infection. The DNA was digested with *Mbo*I (lane M) (New England Biolabs) or *Dpn*I (lane D) (Boehringer Mannheim) according to manufacturer's specifications. Control lanes contain undigested DNA (lane U). *b*, Autoradiogram of the same gel. *c*, Autoradiogram of DNA isolated 15 min post-infection and treated as in *a*. *d*, Autoradiogram of DNA isolated 30 min post-infection and treated as in *a*.

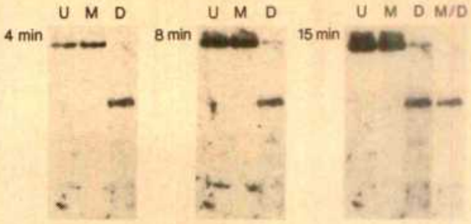

Fig. 3 *Mbo*I and *Dpn*I digestion pattern of integrated Mu DNA isolated from a dam^- strain carrying *him*AΔ82 (RH300). Agarose gels (1%) were run as in Fig. 1. Lanes U, M and D refer to undigested controls, *Mbo*I and *Dpn*I cleaved samples, respectively. The patterns for 4 min, 8 min and 15 min post-infection are shown.

DNA is resistant to *Dpn*I (Fig. 2*d*). These results are consistent with observations that by 30 min after phage induction, Mu DNA is actively undergoing replicative transposition[4,15].

Although most of the integrated Mu DNA appears to be digested with *Dpn*I 8 min after infection, showing that integration had occurred without replication, it would nevertheless be expected that 170 base pairs (bp) or ~0.46% of Mu DNA would still remain linked to *E. coli* DNA, as the first *Dpn*I sites occur 56 bp from the left end and 114 bp from the right end of Mu. A densitometric tracing of the autoradiogram in Fig. 2*b* indicates, however, that about 4% of the integrated DNA remains resistant to *Dpn*I (data not shown). There are several possible explanations of this result, the simplest being that some of the integrated molecules had already entered the subsequent pathway of replicative transposition. To eliminate this possibility, infections were performed into a dam^- host strain carrying *him*AΔ82, a mutation which allows infecting Mu to integrate normally but which does not support the subsequent lytic growth of the phage[16]. In this experiment, integration could be detected as early as 4 min post-infection. The integrated DNA, as in the previous experiment, was susceptible to *Dpn*I, but remained so even 15 min post-infection (Fig. 3). However, 4–8% of the DNA still remained resistant to the enzyme at every time point studied. To test the possibility that this fraction represented a subpopulation of molecules that transposed using the replicative mode, the DNA was double-digested with *Mbo*I and *Dpn*I (Fig. 3, 15 min, lane M/D). If such a subpopulation existed, this fraction would have been hemi-methylated for the entire length of Mu, and would have remained in the high molecular weight region of the gel. However, the *Dpn*I resistant material in lane D no longer remained in the high molecular weight DNA fraction in lane M/D, indicating that it represents partial replication of some or all the integrated Mu molecules. Such replication could be unrelated to the transposition process itself; for example, it could occur by passive replication of the integrated Mu DNA by the *E. coli* replication machinery, or it could be an essential feature of the transposition mechanism which generates simple insertions. It is known, for example, that Mu integration generates a 5-bp duplication at the target site[17,18], which is proposed to arise by a staggered break at the site of insertion and which is subsequently repaired[19]. Some degree of nonspecificity in this process might lead to repair synthesis extending beyond the 5 bp and into Mu sequences. I favour this latter explanation because if the former had been the case, one would have observed an increase in the *Dpn*I resistant material with time, and this did not occur.

Our results indicate that Mu DNA transposition from an infecting phage into the chromosome of its host occurs without a duplication of its genome, in sharp contrast to its subsequent transposition events which are replicative[4]. This then raises questions of what factors govern the choice of the transposition pathway, either simple insertions or co-integrates. One obvious candidate is the physical state of the DNA (although phage DNA is linear, after infection it can be isolated as a non-covalently-closed circular DNA–protein complex[20]). Another possibility is a differential regulation of transposition functions[6]. It is possible that the state of DNA in turn influences the expression of specific proteins.

During the transposition of Tn*3*, the occurrence of an intermediate co-integrate state which is resolved by a site-specific recombination system to produce simple insertions[21], led to the proposal that co-integrates are intermediates in all DNA transpositions[22]. The results reported here prove that is not so. They do not, however, rule out the possibility that there are other circumstances in which simple insertions could arise by a replicative pathway[1].

When determining the molecular mechanism of a non-replicative transposition reaction, the fate of the donor molecule on which the transposable element resides (in the case of infecting Mu, the heterogeneous *E. coli* sequences at its ends) must be considered. The donor molecule may be repaired after the element has 'jumped' out, or may not be repaired. If unrepaired, it would result in the destruction of the donor (either event would be irrelevant for the survival of the infecting Mu phage)[9]. Such a suicidal, non-replicative mode of DNA transposition may explain the occurrence of chromosomal breaks associated with the movement of some transposable elements[23]. One may then raise general questions about the evolutionary significance of replicative versus non-replicative mechanisms for DNA transposition and why different movable elements make the choices they do.

I dedicate this paper to the memory of Ahmad Bukhari. I thank M. Jayaram for many discussions and Richard Lerner for his support. This work was supported by grants from the NSF (PCM8203174) and the NIH (GM33247-01).

Effect of protein packing structure on side-chain methyl rotor conformations

A. A. Kossiakoff*†‡ & S. Shteyn†

Protein molecules undergo a series of conformational fluctuations ranging in degree from atomic vibrations to transient denaturation, even in physiological conditions[1,2]. The rotational motions of amino acid side chains form an important subset of the types of fluctuation a protein can undergo. NMR[3–7] and molecular dynamics[8–10] have shown that methyl groups in proteins are not held in fixed positions, but spin rapidly around their rotor axes. The question then arises as to whether methyl groups in proteins predominantly adopt the 'staggered' conformation, favoured by the intrinsic barrier to rotation of these groups, or whether cooperative packing effects in the folded protein perturb the average configurations to higher torsional energy. We report here an investigation of the rotational conformations of the methyl groups of aliphatic side chains in the protein crambin by neutron diffraction. We find that in the time-averaged structure of this protein, the majority of methyl rotors adopt the staggered conformation. This is consistent with rotation being a quantized event consisting of rapid reorientations of ~120° steps to positions of highest stability. The fact that the local environment does not dictate the low energy state of methyl groups suggests that within the seemingly close-packed interior structure of a protein, mutual packing accommodation occurs as a consequence of the inherent flexibility and small packing defects in protein structures.

Neutron diffraction is an ideal method for investigating methyl group conformation because it allows direct observation of hydrogen atom positions in neutron density maps, and also measurement of the time-averaged structure and thus identification of the lowest energy conformer. Previously, neutron diffraction of trypsin demonstrated that high-resolution data and a well refined phasing model are a prerequisite of any type of detailed methyl rotor analysis[11]. Crambin, a small protein consisting of a single polypeptide chain of 46 amino acid residues[12,13], with 27 terminal methyl groups, therefore makes an ideal candidate for this type of study. Data are obtained from a neutron structure analysis at 1.4 Å resolution. Details of the experimental procedures have been reported previously[14].

Figure 1 shows examples of methyl group neutron densities from the crambin analysis. These densities are taken from a difference map with the density contribution of the methyl carbon subtracted (see Fig. 1). It is clear that for most cases, unambiguous rotor orientations can be assigned from maps of this quality. The rotor density profiles can be displayed graphically by density plots (Fig. 2). These profiles plot the density sampled every 10° around the rotation axis at the stereochemically appropriate location for a possible methyl hydrogen position. Most profiles show a pattern for hydrogen positions every 120° around the rotation axis, which indicates a high degree of order. However, there are a significant number of cases that are disordered by crystallographic criteria. This does not necessarily indicate rotational disorder alone, but could be a function of the inherent vibrational motion of the parent methyl carbon itself and hence of the entire methyl group.

The least well ordered methyl group pictured is Ala 45 CB (Fig. 1*d*). Its corresponding rotor density plot (Fig. 2, symbol +), however, shows a symmetrical profile from which a 'preferred' orientation can be identified. We find in several instances that although the fine structures of this type of curve showed varying degrees of asymmetry (presumably due to residual phasing error), the overall shapes of the profiles generally indicated a systematic trend of peaks and valleys. The rationale in assigning a specific orientation to a rotor is because the peaks and valleys usually appear at intervals of 120°, irrespective of their relative amplitudes. Since no bias was introduced into the maps, the probability of this pattern occurring by chance is remote.

The identification of the highest populated rotor orientation of each methyl group can be assigned most accurately by a 3-fold averaging procedure. In theory, the shape of the resulting

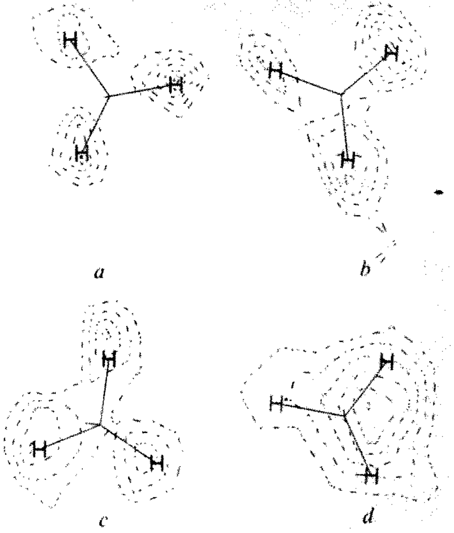

Fig. 1 Sections of the neutron difference Fourier map showing methyl hydrogen densities for several representative methyl groups. The groups shown are: *a*, Ala 24; *b*, Thr 21; *c*, Thr 28; and *d*, Ala 45. Because of the unique scattering characteristics of neutrons by hydrogen atoms, hydrogen atom positions appear in neutron density maps as negative peaks. No phase information about the methyl hydrogens was included in the model; therefore, hydrogens appear in the difference map at their true positions but at reduced density (≃1/2 weight). This crambin analysis represents the first time that methyl hydrogens have ever been observed at atomic resolution in a Fourier density map.

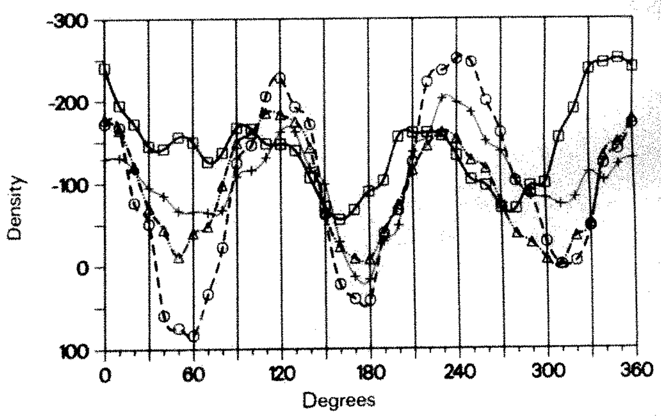

Fig. 2 Examples of representative methyl rotor plots calculated by sampling the map densities in incremental steps around the rotor axes. □, Val 15 CGI; △, Thr 21; ○, Ala 27; +, Ala 45. These plots are derived by calculating a series of possible methyl hydrogen positions at points differing by a rotational increment of 10° and then sampling the observed density at each point in the difference map. Many of the rotor plots have a 3-fold symmetrical pattern, which is due to real structural features since there is no inherent bias in the phasing to produce the 3-fold character. The torsion angle for a staggered conformation is defined here as 0°, 20°, 240° (this corresponds to the usual convention of 60°, 180°, 300°).

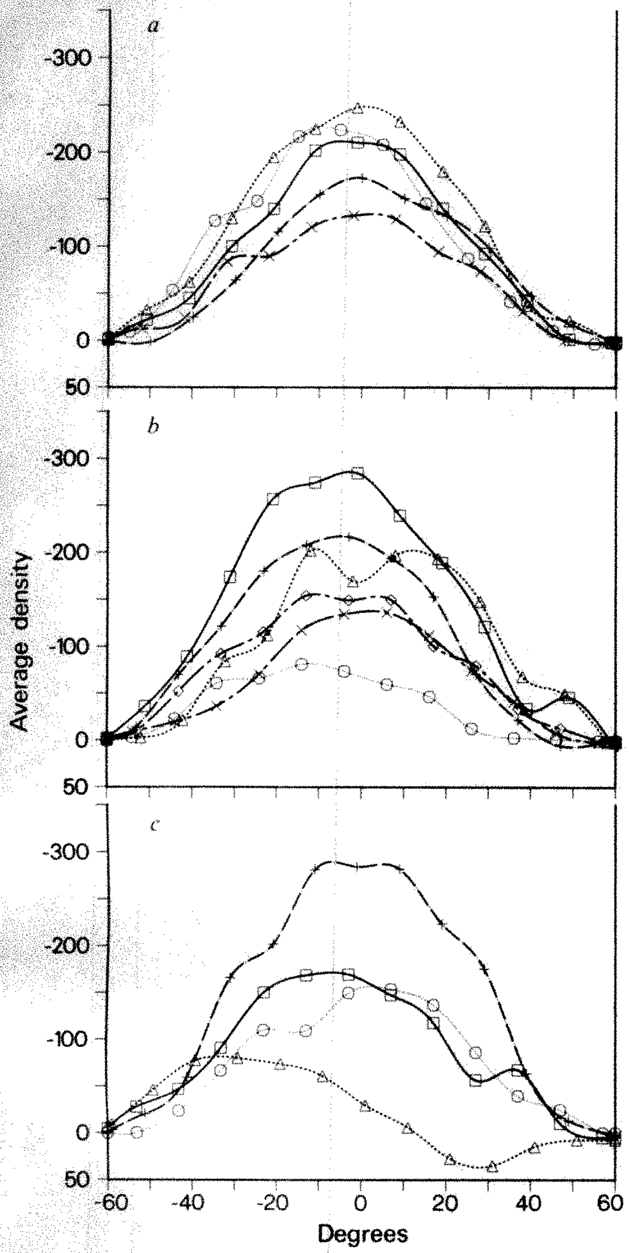

Fig. 3 Rotationally averaged rotor plots for alanine (*a*), threonine (*b*) and valine (*c*). *a*, Ala CB: □ 9, ○ 24, △ 27, + 38, × 45; *b*, Thr CG2: □ 1, ○ 2, △ 21, + 28, × 30, ◇ 39; *c*, Val CG1: □ 8, △ 15; CG2: ○ 8, + 15. Plots were calculated by averaging densities at points separated by 120° in the Fig. 2 type plots (0°, 120°, 240°; 10°, 130°, 250°, etc.). The position of the density maximum defines the group's torsional angle. The staggered conformation is defined as 0°. Plots were placed on the same relative scale by adjusting the lowest average density point for each individual group to be at 0. Effects on the methyl densities due to the inherent vibrational motion of the parent carbon atoms were corrected for by an empirical procedure. This was done by developing an empirical function relating the expected attenuation of the methyl peak density to the vibrating motion (B factor) of the parent carbon atom.

profile curve (Fig. 3) provides useful information on the rotor's characteristic minimum energy, the height and breadth of the curve indicating the rotor's degree of order. Interpretation of these plots, even at the high resolution (1.4 Å) and phasing accuracy ($R = 0.17$) of this analysis, has distinct limitations. Model studies indicate that while the resolution is sufficient to assign precisely the orientation of rotor groups when a position is highly occupied, attempts to discriminate between localized vibrational or static disorder effects are not warranted[15].

Rotationally averaged plots for three representative side-chain types, alanine, threonine and valine, are shown in Fig. 3. Taken together, these plots clearly suggest that the preferred conformations in the large majority of cases is closely staggered. There are, however, a few exceptions to this general observation. The clearest example of this is the CG1 rotor of Val 15 (△, Fig. 3*c*) which is displaced by about 25° from the staggered orientation. This deviation is likely to represent a real effect and not an artefact because the symmetrical nature of the density peaks, each of which is displaced by about 20–30°, is very systematic (□, Fig. 2). We believe this occurs because the CG1 methyl hydrogens make van der Waals' contact with a portion of a symmetry-related molecule in the crystal packing lattice. On the other hand, methyl groups at all other similar intermolecular contact regions do have staggered conformations, so no single generalization applies to these types of interactions.

A significant finding of this study is that a majority of the rotor density plots have distinctive 3-fold symmetry. We suggest that well-defined energy minima for methyl groups exist in protein molecules. (Similar findings were obtained from a trypsin analysis[11], but because the study was done at lower resolution (1.8 Å) the interpretation of the density plots was less definitive.) The staggered conformation of the methyl hydrogens is consistent with the staggered conformations seen around side-chain carbons in high-resolution protein structures determined by X rays. This is a general observation described in many studies. Experimental observations from NMR (showing rapid rotatory motions) together with the neutron diffraction results described here (indicating highly preferred orientations) show that methyl rotations are 'quantized' in 120° steps about a position of highest stability. The lifetime in any particular orientation is short in absolute terms, but it is much longer than times spent in the rotational transition from one 3-fold energy minimum to the next.

The experimental observations presented here address an important question about protein packing. Examination of space-filling models of proteins shows that the groups contained in the interior core are usually extremely close-packed with regard to neighbouring atoms and seemingly have little room to manoeuvre. It might be expected, therefore, that a number of the methyl groups on aliphatic side chains could be forced out of their stable rotatory conformations by packing considerations. Both the crambin and trypsin[16] analyses, however, show that such situations are rare. This implies that the inherent 'breathing' of the protein and its small but numerous packing defects[17,18] allow the methyl groups to adopt the low energy conformation defined by their intrinsic barrier to rotation.

We thank Dr M. Teeter for assistance in the crambin analysis, J. Shpungin and Dr B. P. Schoenborn for technical assistance, and Drs A. Kossiakoff, R. Levy and G. Rose for advice during the preparation of the manuscript. A.A.K. thanks Genentech, Inc. for support during part of the work. 'Z-RNA'—a left-handed RNA double helix

Kathleen Hall, Phillip Cruz, Ignacio Tinoco Jr, Thomas M. Jovin* & Johan H. van de Sande*†

Chemistry Department and Laboratory of Chemical Biodynamics, University of California, Berkeley, California 94720, USA
* Abteilung Molekulare Biologie, Max Planck Institut für Biophysikalische Chemie, D-3400 Göttingen, FDR

In contrast to double-stranded DNA, there has so far been little evidence that double-stranded RNA can undergo major conformational transitions. We have investigated the conformation in different conditions of the double-stranded RNA molecule poly(G-C)·poly(G-C), by NMR, circular dichroism and absorbance spectroscopy. We report here evidence obtained by these different spectroscopic techniques that poly(G-C)·poly(G-C) undergoes a transition from the A-form to a left-handed Z-form in conditions of high ionic strength and at temperatures above 35 °C. This conformational transition may be of relevance to the biological situations in which double-stranded RNA occurs, such as in ribosomes and in some viruses.

Figure 1 shows the phosphorus NMR spectra of three forms of poly[r(G-C)]·poly[r(G-C)]. There are two forms of RNA that are identified by ^{31}P-NMR in the lower salt concentrations, one in 10 mM HEPES where the resonances are separated by 0.40 p.p.m. (Fig. 1*a*) and the other in 3 M $NaClO_4$ where the separation is 0.50 p.p.m. (Fig. 1*b*). In contrast, the spectrum of poly[r(G-C)]·poly[r(G-C)] in 6 M $NaClO_4$ at 45 °C shows a much larger separation of 1.33 p.p.m. (Fig. 1*c*). This pattern is similar to that seen by Patel *et al.*[1] for poly[d(G-m^{5}C)] and poly[d(G-C)] double strands.

The large separation of the phosphorus resonances is characteristic of Z-form DNA[1,2]. The two well-separated ^{31}P resonances have been assigned[3] to the CpG and GpC residues, which in the crystallographic dinucleotide repeat unit have greatly different phosphodiester torsion angles[4]. This produces a zig-zag form with two distinct chemical and magnetic environments for the phosphorus. Our data suggest that the poly[r(G-C)]·poly[r(G-C)] has adopted a Z-form; this conformation will be referred to as Z-RNA.

We have used transient proton nuclear Overhauser effect (NOE) measurements to investigate the conformation about the glycosidic bond. NOE arises from through-space dipolar interactions between spins, and can be observed as a change in intensity of one peak upon irradiating another. These spins must be spatially proximal, as the magnitude of the NOE falls off as $1/r^6$, where r is the distance between the spins. In the Z-DNA structure as determined by X-ray crystallography[4], the guanosine residues adopt a *syn* conformation about the glycosidic bond, and in this form, the guanosine H-8 (GH8) and guanosine H-1' (GH1') protons are only 2.2 Å apart. The guanosine residues adopt an *anti* conformation in A- and B-form, however, and the GH8 to GH1' distance increases to greater than 3.5 Å. Patel *et al.*[1] showed that in low salt, the only NOE from an aromatic proton in poly[d(G-C)]·poly[d(G-C)] was from the cytosine H-6 (CH6) to its neighbouring cytosine H-5 (CH5); these protons are separated by only 2.4 Å. When the polymer was placed in 4 M salt, in addition to the CH6 to CH5 NOE, an NOE was observed between the GH8 and GH1', indicating a transformation to *syn*.

Figure 2*a* shows the proton NMR spectrum of poly[r(G-C)]·poly[r(G-C)] in 6 M $NaClO_4$, 10 mM phosphate, $pD = 7$ at 45 °C. Only resonances due to the GH8 and CH6 protons appear in the region between 7 and 8 p.p.m., and the peak at 7.82 p.p.m. has been assigned to the GH8 using deuterium exchange at high temperature. The GH8 shows a large NOE to a resonance at 5.7 p.p.m., which is assigned to the GH1' (Fig. 2*b*). The presence of this NOE shows that the guanosine residues adopt the *syn* conformation. These NOE measurements, together with the phosphorus NMR data, provide the basis for designating the high salt form of poly[r(G-C)]·poly[r(G-C)] as Z-RNA. The CH6 proton also shows a large NOE (Fig. 2*c*) to a peak at 5.17 p.p.m., which has been assigned to the neighbouring CH5.

Figure 3*a* shows the proton NMR spectrum of poly[r(G-C)]·poly[r(G-C)] in 3 M $NaClO_4$, 10 mM $NaPO_4$, $pD = 7$, at 45 °C. Deuterium exchange at high temperature was used to assign the resonance at 7.51 p.p.m. to the GH8 proton. In the

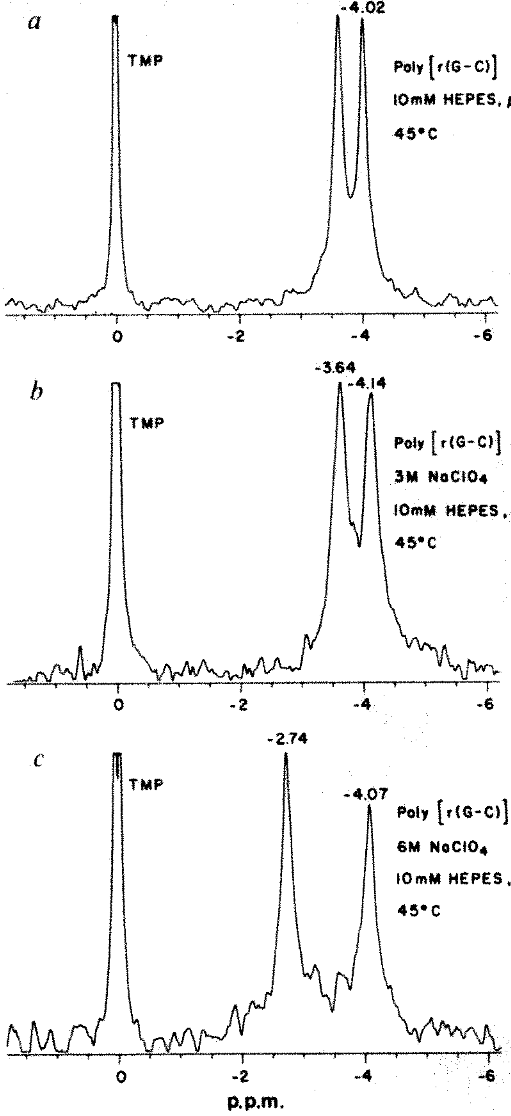

Fig. 1 Phosphorus NMR spectra of poly[r(G-C)]·poly[r(G-C)] in three ionic strengths at 45 °C. *a*, Poly[r(G-C)]·poly[r(G-C)] with no added $NaClO_4$. *b*, Poly[r(G-C)]·poly[r(G-C)] in 3 M $NaClO_4$. *c*, Poly[r(G-C)]·poly[r(G-C)] in 6 M $NaClO_4$.

Methods: The polymer was prepared using *Escherichia coli* RNA polymerase on a poly[d(I-C)]·poly[d(I-C)] template[12]. Polymer size was determined by polyacrylamide gel electrophoresis in denaturing conditions. Size markers of simian virus 40 *Hinf* I digests were used for comparison. The size distribution ranged from 40 to 800 nucleotides, most being 150–500 nucleotides. The DNA template was removed by DNase I digestion; removal was complete as assessed by optical melting and CD data. Spectra were obtained at 81.75 MHz on the UCB-200 spectrometer (200 MHz proton), using broad-band proton decoupling. Each sample contained approximately 30 mM (in nucleotides) of the polymer, 10 mM HEPES, *p*H 7.0, 0.1 mM EDTA; chemical shifts are referenced to the internal standard, trimethyl phosphate (TMP).

---

† Present address: Department of Medical Biochemistry, University of Calgary, Calgary, Alberta, Canada T2N 4N1.

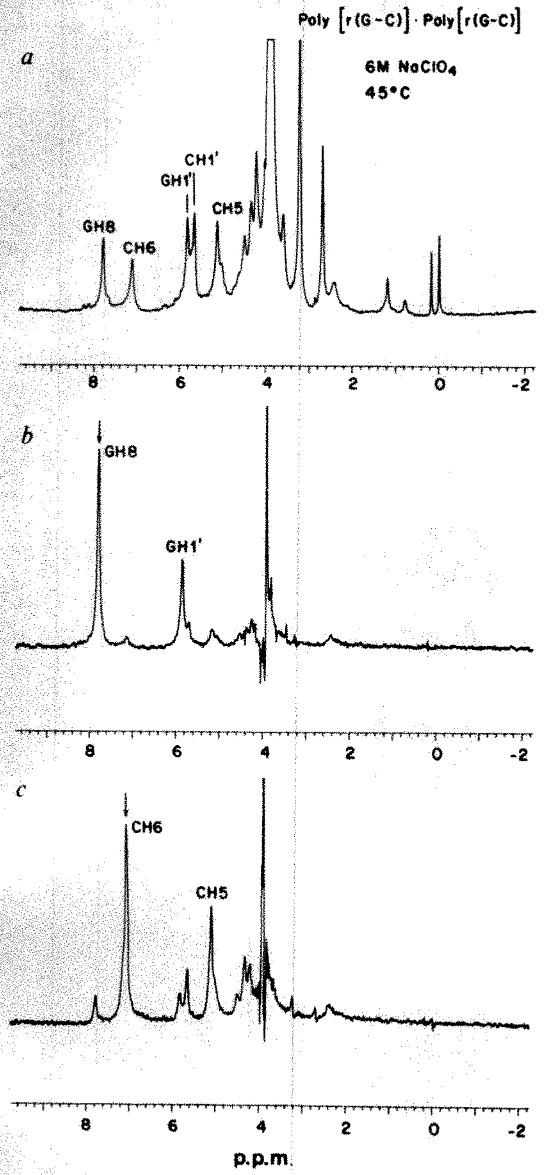

Fig. 2 Proton NMR spectra at 500 MHz of poly[r(G-C)]·poly[r(G-C)] (~30 mM in nucleotides) at 45 °C in 6 M $NaClO_4$, 10 mM phosphate buffer, *p*H 7.0, and ~0.1 mM EDTA. Chemical shifts are referenced to the internal standard trimethylsilyl propionate (TSP). Spectra were obtained on the JEOL GX-500 instrument at the Stanford University NMR Center. *a*, Spectrum in D_2O. The large narrow resonances below 5 p.p.m. correspond to residual solvent protons, EDTA and reference TSP. *b*, Transient NOE difference spectrum obtained by irradiating the GH8 proton (indicated by an arrow) with a 50-ms saturation pulse before obtaining the spectrum. The difference spectrum represents the spectrum with an on-resonance presaturation pulse subtracted from the spectrum with the presaturation pulse 10 kHz off resonance. A large NOE to the GH1′ is observed. The reverse experiment (not shown) results in NOE to the GH8 proton on irradiation of the GH1′. *c*, Transient NOE difference spectrum obtained by irradiating the CH6 proton (indicated by an arrow) as described above. A large NOE can be seen to the CH5 proton. Irradiation of the CH5 proton results in a large NOE to the CH6 (not shown).

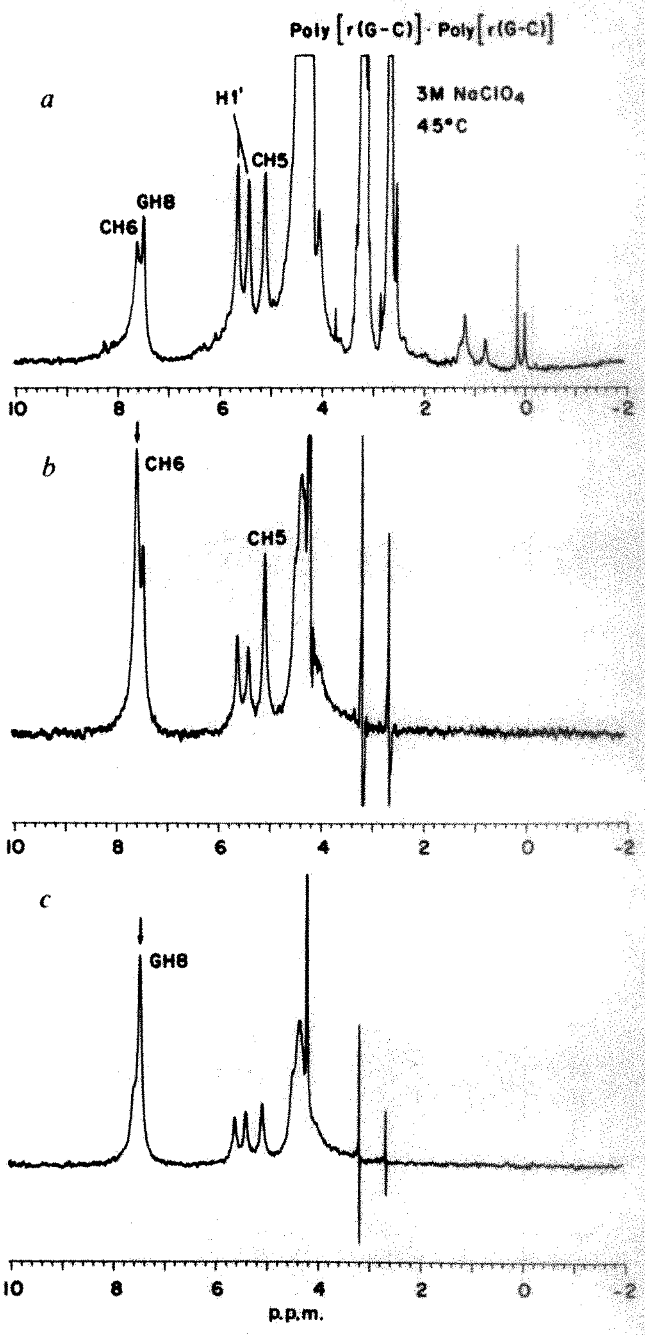

Fig. 3 Proton NMR spectra of poly[r(G-C)]·poly[r(G-C)] in 3 M $NaClO_4$. All other conditions are as described in the legend to Fig. 2. *a*, Spectrum at 500 MHz in D_2O. *b*, Transient NOE difference spectrum obtained by irradiating the CH6 proton (indicated by an arrow) as explained in Fig. 2 legend. A large NOE to the CH5 is observed. *c*, Transient NOE difference spectrum obtained by irradiating the GH8 proton (indicated by an arrow). Only small NOEs due to spin diffusion are observed.

A-form, exchange is extremely slow; this is in contrast to the Z-form, which exchanges more rapidly. Therefore, to promote deuterium exchange, the poly[r(G-C)]·poly[r(G-C)] was heated to 80 °C for several hours in 1 mM Na phosphate, 0.1 mM EDTA.

Figure 3*b*, *c* shows the NOE difference spectra of poly[r(G-C)]·poly[r(G-C)] in 3 M $NaClO_4$ that result upon irradiation of the peaks at 7.63 and 7.51 p.p.m., respectively. Saturating the CH6 peak at 7.63 p.p.m. results in a large NOE to a peak at 5.11 p.p.m.; this peak has been assigned to CH5. When the GH8 peak at 7.51 p.p.m. was irradiated, only several small NOEs were observed, indicating that guanosine is in the *anti* conformation. It is seen from the NOE spectra that there is a significant amount of spin diffusion among the various protons. This was also seen with poly[d(G-C)] (ref. 1) and can to some extent be diminished by shortening the duration of the saturation pulse. It was not entirely eliminated in these experiments, however, and appears as small NOEs in all the spectra.

The absorption and the circular dichroism (CD) spectra of two forms of RNA (Fig. 4) corroborate the NMR conclusions. The Z-RNA absorption spectrum (6 M $NaClO_4$, 45 °C) has a

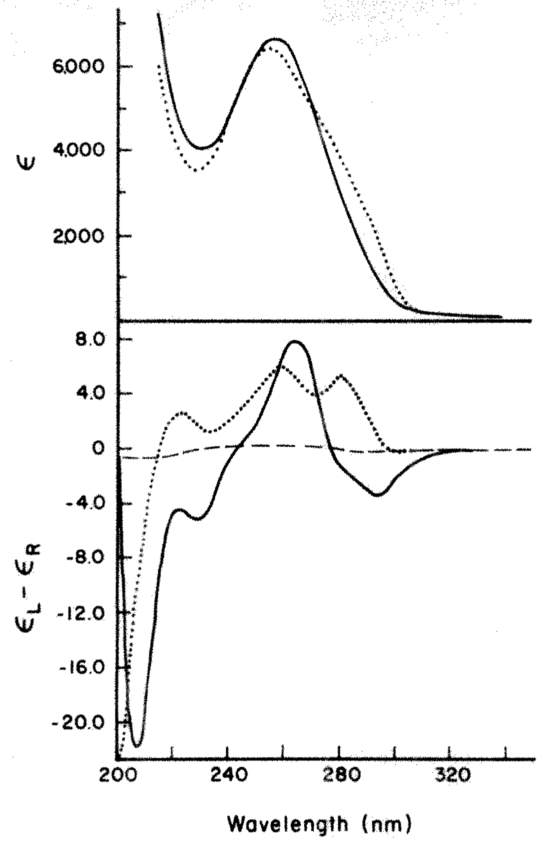

Fig. 4 Absorption (top) and CD (bottom) spectra of two forms of poly[r(G-C)]·poly[r(G-C)]. Absorption spectra were measured with a Gilford model 250 spectrophotometer; CD spectra were measured with a JASCO J500C spectropolarimeter. Both instruments have thermoelectric cell blocks. The absorbance and CD were measured in 10 mM phosphate, *p*H = 7.0, 6 M $NaClO_4$ at 22 °C (solid line) and 45 °C (dotted line). An extinction coefficient of 6,560 at 260 nm was used for the poly[r(G-C)] at 22 °C (ref. 6). The CD spectrum at 22 °C is similar, but not identical to the spectrum seen in buffer alone. It is identical to that for the polymer in 3 M $NaClO_4$. At 45 °C, 6 M $NaClO_4$ the CD spectrum is identical to that seen in conditions of lower perchlorate and higher temperatures, and is similar to that in 20% (v/v) ethanol in 4.8 M $NaClO_4$.

shoulder at 290 nm; this is very similar to the spectrum of Z-DNA (ref. 5). Two types of CD spectra are seen for poly[r(G-C)]. The first is represented by the spectrum at 6 M $NaClO_4$, 22 °C. It is identical to the CD spectrum in 3 M $NaClO_4$ and is similar to a CD spectrum measured in 10 mM sodium phosphate (not shown) which matches the CD spectrum of Gray *et al.*[6] in 1 mM Na phosphate, 0.1 mM EDTA, *p*H 7.8. These CD spectra are all presumed to be from an A-type conformation of the poly[r(G-C)] (ref. 7). Because the CD spectrum of the polymer in 6 M $NaClO_4$, 22 °C and 3 M $NaClO_4$ are identical, we used the latter solvent at 45 °C for NMR experiments; at 22 °C the NMR linewidths are too broad for analysis. The CD spectra in dilute phosphate differ from those in $NaClO_4$ by a small change in the band at 285 nm. This band is particularly sensitive to solvent, and diminishes at high ionic strength. This CD band may be correlated with the small differences in phosphorus resonances between the RNA in 10 mM HEPES and in 3 M $NaClO_4$.

The CD spectrum in 6 M $NaClO_4$, 45 °C is very different from the others, and is identified as that of Z-RNA. The CD remains positive in the region above 215 nm. The negative bands above 280 nm and below 240 nm in A-RNA change sign in Z-RNA; the positive band near 260 nm remains positive.

The transition temperature for the A- to Z-RNA transition is a function of the solvent conditions. In 6 M $NaClO_4$, the transition temperature is ~35 °C; in 4.8 M, it is ~45 °C; in 4 M, ~80 °C; in 3 M, it is above 80 °C and not measurable in our instrument. The addition of ethanol to the perchlorate solution decreases the transition temperature, so that in 4.8 M $NaClO_4$/20% ethanol, the RNA is in Z-form at room temperature. This temperature dependence of the transition to Z-RNA form is analogous to that of poly[d(G-C)]·poly[d(G-C)]. For that polynucleotide, the Z-form is favoured at higher temperatures in LiCl or ethanol/water solutions[1,8,9]. However, we have found that solvents which will cause a B to Z transition in poly [d(G-C)], such as 4 M NaCl or 1 M $MgCl_2$, do not cause an A to Z transition in poly[r(G-C)]. This is consistent with the work of Westerink *et al.*[10] and Uesugi *et al.*[7] who found no Z transition in these salt solutions for r(G-C) oligonucleotides.

The kinetics of the transition also vary with the solvent and the temperature. In 6 M $NaClO_4$, a temperature shift from 22 °C to 35 °C results in an A- to Z-RNA transition which takes ~1 h. The reverse transition occurs over 5 h. A temperature shift from 22 °C to 45 °C (or addition of 20% (v/v) ethanol and concomitant dilution to 4.8 M $NaClO_4$), however, produces the Z-RNA form in ~10 min, although again the reverse transition on lowering the temperature from 45 °C to 22 °C takes several hours.

This is the first major conformational change reported for a double-stranded RNA; it shows that RNA has conformational lability, contrary to current belief. It is consistent with the finding of Uesugi *et al.*[11] that r(C-m^{8}G-C-m^{8}G) exists in a Z-like structure. The transition to Z-form RNA requires more extreme conditions than the transition to Z-form DNA. However, in analogy to Z-DNA, other more physiological environments may be found to favour Z-RNA, and other RNA sequences may also undergo the transition. In any case one should now consider conformations other than A-form when considering double-stranded regions of RNA in ribosomes, viruses and other RNA-protein complexes.

We thank Professor Michael Chamberlin and his laboratory for providing us with RNA polymerase as well as advice on the synthesis and purification of poly[r(G-C)]·poly[r(G-C)]. We also thank Dr Dave Wilbur for assistance on the GX-500 spectrometer at Stanford. The proton NMR experiments were performed at Stanford University NMR Center, which is supported by NSF grant GP23633 and NIH grant RR00711. The work at Berkeley was supported in part by NIH grant GM10840 and the US Department of Energy, Office of Energy Research, under contract 03-82ER60090.000.

Erratum

Dynamics of meltwater discharge from Northern Hemisphere ice sheets during the last deglaciation

R. H. Fillon & D. F. Williams

Nature **310,** 674–677 (1984)

IN the above letter, the last four lines of the penultimate paragraph on p. 676 ('anomaly areas... $\delta^{18}O_{sw}$ anomaly') are a repetition from a previous paragraph. The correct four lines read:

amount of meltwater discharged into the Canadian Current before 13 kyr BP according to our calculations. This excess may reflect an early marine-drawdown phase of North American deglaciation[4,23].

Preformation to punctuation

Colin Patterson

Evolution: The History of an Idea. By Peter J. Bowler.
University of California Press: 1984. Pp. 412.
Hbk $34.45, £23.95; pbk $12.60, £8.75.

I CAME to this excellent book with vague misgivings, remembering the tedium of Henry Fairfield Osborn's *From the Greeks to Darwin*, or Edward Clodd's *Pioneers of Evolution*. No need to worry, for neither is cited in Peter Bowler's massive 54-page bibliography, and history of science is long past relentless progress towards today's truth, as chronicled in those older works. But Bowler does say that

> A few years ago, it would have been difficult to write a history of evolutionism except from the perspective that the modern form of Darwinism represents a triumphant climax to the process.

To my real surprise, I learned from Bowler's bibliography that his book has no real competitor — there is no modern, general history of evolutionism. The closest competitors, I suppose, are D.R. Oldroyd's *Darwinian Impacts* (Open University Press, 1980), and Ernst Mayr's magnum opus, *The Growth of Biological Thought* (Harvard University Press, 1982). In his opening chapter Bowler notes, and denies, the distinction between "internalist" and "externalist" historians of science, the first studying the "objective process of scientific discovery", the second looking at "how society reacted". He argues that the distinction disappears once we realize that scientific knowledge is not purely objective; perhaps, but one would have to rate Oldroyd's book as more externalist than Bowler's, and Mayr's as more internalist. Both are more difficult going. Bowler aims at readers with no background in either biology or history, especially students in history of science, but I believe that most biologists and many other scientists could read him with pleasure and profit.

The book is finely and carefully balanced, as exemplified by the arrival of *On the Origin of Species* exactly midway through the text, so that half the book is pre-1859, and half after that date. Bowler has particular strengths in both halves, for he has published in history of biology from seventeenth-century theories of reproduction to twentieth-century genetics, notably in books on nineteenth-century palaeontology (*Fossils and Progress*; Science History Publications, 1976) and on "anti-selectionism" around 1900 (*The Eclipse of Darwinism*; Johns Hopkins University Press, 1983). Throughout the book, I was struck by the way Bowler compresses complicated ideas into a page or two, and still finds space for illuminating comment: someone who can do this even for so thoroughly studied a figure as Darwin (for example on pp. 142–146) is doing excellent work.

There are two technical blemishes, the first trifling, of the kind it pleases pedants to discover — the portrait on the dust-jacket, said to be of J.B.S. Haldane, is his father J.S. The second blemish, more intrusive, is Bowler's usage of the word "hierarchy", a vital and recurring concept in the history of evolution. He uses "hierarchy" to mean linear sequence, as in the "chain of being" or a chain of command, where the general's orders pass down the military hierarchy to the private. But in biology today, "hierarchy" entails the inclusion relation, so that the higher includes the lower rather than outranks it: this usage is definitive in taxonomy, but also general in ontogenetic theory and other fields invoking theories or processes of branching. Bowler's idiosyncratic or old-fashioned usage leads to apparently nonsensical statements such as "Linnaeus' system [of classification]...does not imply a hierarchical ranking" or "Cuvier's reluctance to accept hierarchical classification"—here the notion of branching, or inclusion, is seen as the antonym of hierarchy.

The book ends with a chapter on "The Modern Debates", picking out four or five areas of controversy. Surprisingly neutralism, and the associated "molecular clock", get no mention here. Indeed, neutralism receives very short shrift in the book, three passing mentions, one of which is mistaken:

> If the survival of the fittest were necessarily true, it would be impossible for anyone to imagine that it was false—yet there have been theories of evolution based on random factors that deny the superior reproductive power of the fit.

The mistake here is to equate natural selection with change (directional selection), whereas neutralists emphasize the dominance of stabilizing selection, which resists change. Neutral theory seems to me to deserve at least as much space as punctuated equilibrium, which gets a very fair hearing, and modern Creationism, which gets 11 pages. But one point in those pages deserves thought:

> It may sound paradoxical, but the only way creationists can be forced to expose their own extraordinary theory to close analysis is if evolutionists concede that they cannot prove their own case. It is only by admitting the lack of certainty inherent in any theory that we can shift the argument to a new level.

Bowler occasionally slips from that noble level, as with "The true story of the horse's evolution has turned out to be rather more complicated" and similar comments implying access to the truth on human evolution. But all in all, I salute what I believe is a superb job. □

Records of the early metazoans

Steven M. Stanley

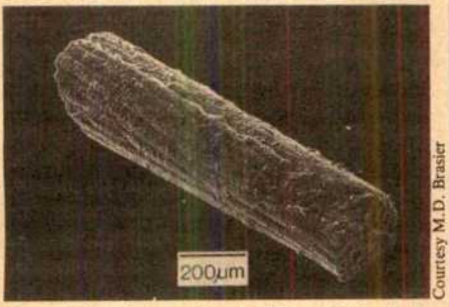
The Dawn of Animal Life: A Biohistorical Study.
By Martin F. Glaessner.
Cambridge University Press: 1984.
Pp. 244. £25, $49.50.

FOR nearly a century after Darwin published *On the Origin of Species*, the nature of Precambrian life was debated fruitlessly in a climate of empirical uncertainty. Early fossil finds were continually announced and continually debunked, so that in any given year some claims were alive but clearly vulnerable to rejection.

During the 1950s and 1960s, the discovery of four types of Precambrian and earliest Cambrian fossils altered the picture dramatically, adding greatly to the temporal range of palaeontological inquiry. The four new fossil groups were single cells preserved in fine-grained sedimentary rocks; imprints of soft-bodied animals; tiny skeletal fossils slightly older than the first Cambrian trilobites; and trace fossils (tracks, trails and burrows). Of the four, single cells have often been seen as the most exciting finds, partly because their record extends some 2×10^9 years further back in time than the record of multicellular life. In many ways, however, the study of Precambrian cells has been disappointing: increase in cell size and surface complexity about 1.4×10^9 years ago point to the primary expansion of eukaryotes at this time, but the fossil record reveals little about the biological nature of earlier prokaryotic cells. The early metazoan record has been far more revealing, and we must welcome Martin Glaessner's publication of a book that focuses on this record, pulling together our knowledge, while briefly reviewing Precambrian microfossils. Glaessner, a pioneer in the study of Precambrian metazoans, has kept abreast of new developments, including many in the Soviet Union that have gone largely unnoticed elsewhere.

As might be expected, Glaessner devotes about half of his book to the spectacular

Ediacara soft-bodied fauna of Australia, which he first elucidated in 1958 and 1959, and to similar but less rich faunas that have since been discovered in many other parts of the world. The treatment of these faunas is the most comprehensive yet and is perhaps weakened only by the paucity of photographs — written descriptions of important morphological and preservational features leave the reader no recourse but to seek illustrative material among the other works cited in the book. In Glaessner's interpretation, the Ediacara fauna is dominated by medusoid and sea-pen-like coelenterates as well as annelids and arthropods. Unfortunately, the book was published too soon for the author to respond to Professor A. Seilacher of Tübingen, who is currently challenging these taxonomic assignments. Perhaps the need for a response will prompt Professor Glaessner to provide another review with plentiful photographs of high quality. Glaessner's global reviews of Late Precambrian trace fossils and Tommotian (earliest Cambrian) shelly fossils are also comprehensive and authoritative, though unfortunately they are even less well illustrated.



Courtesy M.D. Brasier

Part of the picture of early life — *Coleoloides typicalis*, a calcareous tubular fossil from the earliest Cambrian Hyolithes Limestone of Nuneaton, UK.

A nagging question that remains in Precambrian palaeontology is: when did the metazoans actually originate? Trace and body fossils reveal the presence of metazoans in considerable diversity after the end of the Varangian glaciation, about 6.5×10^8 years ago, but what about an earlier history? Glaessner concludes that the metazoan record extends to about 1×10^9 years before the present, but the evidence he cites is meagre and equivocal. If some of the alleged trace fossils are real, the suppression of metazoan diversification for several hundred million years remains one of the greatest puzzles in palaeontology.

Although Glaessner has been unable to shed much light on this problem, his book does provide a unique, up-to-date evaluation of Late Precambrian life. It should expand the knowledge of all palaeontologists, save a few specialists, and serve as a basis for graduate seminars on the early diversification of metazoan life. □

Gauge theories with a difference

Graham G. Ross

Quarks and Leptons: An Introductory Course in Modern Particle Physics.
By Francis Halzen and Alan D. Martin.
Wiley: 1984. Pp. 396. Hbk £35.45, $31.95; pbk £12.50, $13.75.
Gauge Theories of the Strong, Weak, and Electromagnetic Interactions. Frontiers in Physics.
By Chris Quigg.
Benjamin-Cummings/Addison Wesley: 1984. Pp. 334. $42.95, £33.60.
Gauge Theory of Elementary Particle Physics.
By Ta-Pei Cheng and Ling-Fong Li.
Clarendon: 1984. Pp. 450. Hbk £35, $39.95; pbk £15.
Gauge Theories of Strong and Electroweak Interactions.
By P. Becher, M. Böhm and H. Joos.
Wiley: 1984. Pp. 306. £28, $54.95.

IT IS indicative of the state of high energy physics that four textbooks should appear together covering broadly the same ground. In recent years gauge field theories have emerged for the strong and the weak interactions, complementing quantum electrodynamics, the remarkably successful theory of the electromagnetic interaction. A large amount of experimental data has now accumulated consistent with the predictions of these theories, culminating with the detection of the gluons (the strong interaction partners of the photon) and of the $W^\pm$ and Z intermediate vector bosons (the weak interaction partners of the photon).

After the success of these theories there has been something of a lull in theoretical activity, leaving time for reflection and organization. The four books reviewed here are products of this period and all introduce the subject of local gauge field theories and their application in particle physics. However each book has a character of its own and addresses a different level of audience.

Pitched at an introductory level is the book by Halzen and Martin. It acquaints the reader with the nature of the fundamental interactions and the fundamental building blocks of matter, quarks and leptons, and is at its best in the explicit treatment of the use of Feynman rules to calculate physical processes at tree level. Many worked examples are given (with all the steps) and the text is supplemented by a large number of instructive problems; together, these features should enable readers with no prior knowledge in the subject to calculate simple processes for themselves.

The treatment of fermions and the early introduction of a chiral basis for Dirac matrices is clear and thorough, but somewhat less successful is the treatment of the group theory which falls short of being really useful. Beyond the tree level the book is, possibly necessarily, less explicit. While I was disappointed that the introduction of local gauge theories and the Lagrangian formalism was left to the penultimate chapter — too late for a thorough treatment — I liked this book in general. Above all it should prove to be a *useful* part of an introductory course in particle physics.

In many ways, Chris Quigg starts where Halzen and Martin leave off. After a nice introduction to quarks, leptons and gauge bosons, local gauge field theories are introduced via the Lagrangian formalism. In the main, the reader is expected to be able to calculate Born graphs, leaving space for a fuller discussion of quantum chromodynamics (QCD — the gauge theory of the strong interactions) and of spontaneously broken gauge theories used in describing the weak interactions.

There is a good discussion of radiative corrections in QCD, well motivated by explicit calculations and leading to a Feynman graph analysis of the leading log summation, but it stops short of the renormalization group analysis needed to justify and simplify this summation. The general emphasis is on explicit physical applications, the book containing good coverage of deep inelastic scattering, $\gamma\gamma$ scattering and e^+e^- annihilation. The treatment of the electroweak theory is easy to follow but is only at tree level; no attempt is made to present a loop calculation in a spontaneously broken gauge theory. The book ends with a brief but helpful discussion of the extension to grand unified theories, in particular to SU(5). Throughout problems are set, carefully chosen to augment and illustrate the textual discussion, while the extensive reference list will help readers delve further into particular topics. Overall this is a good introductory book, with plenty of physical insights, and will repay study.

By far the longest book of the four is that by Cheng and Li. It is also the most ambitious in terms of the subject matter covered, with emphasis more on the theoretical aspects. Part One covers the formal aspects of field theory, group theory and chiral symmetry in strong interactions, as well as the construction of local gauge field theories, their Feynman rules and the calculation of radiative corrections. All this should be useful to theoretical students with some prior knowledge for it neatly summarizes a vast subject. Because of its wide scope, however, there is necessarily little time for elaboration and I think this part would be heavy going for a newcomer to the field. Renormalization and the renormalization group are discussed in detail and this aspect of the book would complement the more physical analysis in terms of Feynman graphs presented, for example, by Quigg.

In Part Two, Cheng and Li move on to

QCD and the electroweak theory. I particularly appreciated inclusion of an explicit treatment of loop calculations in a spontaneously broken gauge theory, and also the detailed discussion of the Kobayashi–Maskawa matrix, CP violation and neutrino masses. All in all the book contains a lot of goodies, including grand unification and nonperturbative aspects of gauge theories; but, again, one probably needs some experience to appreciate them, for often an historical approach is followed which hinders the logical development of the subject. For example, a detailed discussion of the role of light-cone singularities in the Bjorken scaling region precedes the more modern and more physical momentum space Feynman graph analysis. Also there are no set problems to guide the reader. Ideally, then, Cheng and Li's book should be read after one (or both!) of the more introductory texts discussed above.

The fourth book, by Becher, Böhm and Joos, is a translation of the German edition which first appeared in 1981. It is different in character to the others, delving deeper into the theory of the renormalization of the gauge field theory. This is more in the nature of an advanced text or review for an experienced theoretician and contains extensive discussions, without full details of intermediate steps, of perturbative and nonperturbative aspects of QCD. The account of the electroweak theory, on the other hand, is briefer but more straightforward with a nice discussion of the high energy behaviour of Yang–Mills gauge theories.

Although the four texts reviewed here have as a general theme the gauge theories of the fundamental interactions, they vary widely in their demands on the reader. To a large extent they complement one another, and together represent a substantial improvement in the literature surveying modern particle physics. □

Graham G. Ross is in the Department of Theoretical Physics at the University of Oxford.

Pastures of muscle physiology

D.R. Wilkie

Muscles, Reflexes, and Locomotion.
By Thomas A. McMahon.
Princeton University Press: 1984. Pp.331. Hbk $50, £50; pbk $15, £12.50.

THIS is a brilliant book. Dr McMahon's original training as an engineer is an excellent one for a physiologist; in both branches of science we are concerned with machines that must function in an optimal way. Here we are provided with a clear and accurate summary of many of the mathematical aspects of muscular function that otherwise demand a laborious appraisal of a large number of original papers. Our understanding (and diligence) are repeatedly challenged by the examples and questions to be found at the end of every chapter.

McMahon's wide and scholarly approach to his subject, and his limpid and often witty style of writing, enable him to illuminate a whole range of topics ranging in physical scale (though not necessarily in complexity!) from the mode of operation of the individual cross-bridges thought to generate mechanical power at the molecular level, to the problems inherent in designing an elephant and in building a "tuned" running track on which athletes have consistently produced improved performances.

Naturally I do not agree with every word in the book. For example, McMahon writes (p.35) "The discovery of a process which apparently absorbs heat, like the mechanism of a refrigerator, provided a great deal of entertainment in the muscle literature for years". Alas he does not make it nearly clear enough for my liking that the "entertainment" resulted in deep confusion which lasts to this day. There are no circumstances in which a muscle acts as a refrigerator, which is a machine that moves heat from a lower to a higher temperature by the continued application of mechanical or electrical power. Nor can I see how a "unifying principle" (p.79) is provided by the non-uniformity of sarcomere lengths. The question of the instability of stretched muscle fibres, whose tension–length curve has a negative slope, has been discussed for many years yet remains controversial. In whole anatomical muscles (rather than in isolated single fibres) an important role, probably a stabilizing one, may well be played by the connective tissue between the fibres which is plentiful and unlikely to be arranged at random. Microanatomical studies are much needed; until they have been carried out, comparison between isolated muscle fibres and intact anatomical muscle demands great caution.

The biochemical aspects of muscular function are touched on only lightly (nobody should expect everything!) but McMahon is careful to differentiate between the chemical processes and the physical energy — heat and work — that results from them. A widespread failure to make this distinction is at the root of the continuing confusion about a topic introduced on page 211, that of positive and negative work. In movements of a whole animal, the function of muscles as brakes *absorbing* mechanical work is almost as important as their function as motors *producing* mechanical work. Unlike mechanical brakes, however, the muscles consume fuel in performing their braking action and even in sustaining a static load. To pursue the mechanical analogy further, a motor car can stop indefinitely on a hill by applying the brake and stopping the engine. A muscle must rev the engine and slip the clutch. The definition of "efficiency" given in Eqn 8.3 is ambiguous concerning positive and negative signs, though they can be inferred from the left-hand lines in Fig. 8.21 which do indicate negative values of "efficiency". This is formally correct though perhaps not very helpful. I hope that this section will make the topic as clear to the uninitiated as I know it to be to the author himself.

The last chapter, "Effects of Scale", is a delight to read and may well come as a surprise to biologists who work on subjects other than muscular contraction. Experimentally, we find in animals of different size a large number of functions that depend in a highly regular way on body weight, but in hardly a single case is there a satisfactory physical or biochemical explanation for the dependence. McMahon explores various possibilities in a way that is both instructive and entertaining. The relationship between metabolic rate and body weight is the best-established of such laws and is referred to briefly on page 279. It is known to apply to living creatures over a weight range of 10^{18}, a respectable number even by astronomical standards, yet it totally lacks an adequate explanation. This seeming vacuum is a constant source of irritation to all biologists who concern themselves with such issues. Presumably because of their recent publication dates, no references are given to the fuller analyses of the problems of scale given in the beautifully-illustrated books by McMahon and John Tyler Bonner (*On Size and Life*; W.H. Freeman, 1983) and by Knut Schmidt-Nielsen (*Scaling: Why is Animal Size so Important?*; Cambridge University Press, 1984).

Students of muscle physiology at all levels will benefit from reading *Muscles, Reflexes, and Locomotion*. Not only is it a compact source of information, but a novel, comprehensive and readable book which tempts one to browse in the wider pastures opened up by Dr McMahon. □

Job prospects in the United States

from Richard Pearson

With the United States' economic boom continuing, and the rate of job generation far outstripping that of other Western economies, what are the job prospects for life scientists and engineers?

PROJECTING future employment levels is notoriously difficult, yet for occupations requiring many years of training and experience, insights into future employment patterns and imbalances can show where significant adjustments might be needed in labour market and training policies. Any forecasts, however, can only be as good as the assumptions on which they are based, and these need to involve assessments of future levels of economic and investment activity, and technological and productivity changes.

Although scientists, engineers and technicians account for only a small fraction of the US workforce (less than 5 per cent), they have a disproportionate role in economic growth, technical innovation and national security and are a key area of concern. A key role for the governmental National Science Foundation (NSF) in Washington is to provide information on the availability, both current and projected, of such scientific and technical resources in the United States. A recent NSF study looks at the ability of the labour force to fuel the expected 45 per cent increase in defence expenditure over the period 1982 to 1987 (see Table 1). A series of scenarios was used, looking at the implications of high and low growth rates in Gross Domestic Product between 2 and 4 per cent per year, and of two defence expenditure scenarios averaging 3 and 8 per cent per year growth.

Table 1 Projected US employment changes for the years 1982–87

	Employment (thousands)		
	1982	1987 (low growth)	1987 (high growth)
Computer scientists	219	287	303
Other scientists	508	556	585
Engineers	1,140	1,296	1,423
Technicians	1,468	1,649	1,760

Values for 1982 are 'actual', and those for 1987 are projected. Source: *Projected Response of the Science Engineering, and Technician Labor Market to Defense and Non-Defense Needs: 1982–87* (National Science Foundation, Washington, 1984).

Growth in demand for scientific engineering and technician (SET) manpower is expected to grow by between 2.6 and 4.1 per cent per year, a rate of growth higher than for employment generally (up 1–2.4 per cent per year). This increasing demand is driven not only by the strong performance of high technology industries, with their high concentrations of SET manpower, but more importantly by the diffusion of technology throughout the economy, which has led to a significant shift in staffing patterns towards SET employment. Interestingly, although each scenario focuses on rather different sets of assumptions, the projected range of SET requirements is rather more restricted, never varying by more than 5 per cent from the average 1987 projected value in any of the major occupational categories (Table 1). This is in part because SET manpower is only a small proportion of all jobs in the economy but also because productivity increases at a much faster rate under the high growth scenario, with the productivity gains counterbalancing the employment impact of economic growth which in turn reduces the need for additional SET manpower.

There were nearly 750,000 university degree level science jobs in the US economy in 1982 and this figure was expected to grow by between 116,000 (3 per cent per year) and 161,000 (4.1 per cent per year) jobs over the period to 1987. Both these figures represent a slow-down in the 8.7 per cent average annual growth rate over the period 1977–1982. The key determinants of these growth patterns are shown to be primarily economy-related, with the key driving forces for increased scientific jobs being the service sectors, particularly research and development laboratories, consulting firms and computer establishments.

The engine of this growth in science jobs seems to be the computer, with computer systems analysts, an occupation first recognized officially in the 1970 census, accounting for about 300,000 people in 1987, regardless of the scenario followed, with half of them employed in business services. The growth in these jobs will average about 6 per cent per year, the net growth being 70,000–85,000 jobs over the five years. Computer specialists are expected to dominate science jobs in 1987, increasing their share over the period from 34 to 55 per cent, with psychologists, chemists and mathematicians being the other largest groups.

Of the physical sciences, physics has the fastest growth at 1.4 to 3 per cent per year with growth for chemists being rather lower, at 1.5–2.5 per cent, a figure similar to that for geologists. Mathematical science is projected to have rather faster growth at 2.2–3.5 per cent per year but the total job gain will only be 5,000–10,000 jobs overall. In the life sciences, agricultural jobs barely keep pace with overall employment growth, and while the number of jobs for biological scientists will grow rather faster, the total job gain will be only about 5,000–10,000 extra jobs.

By way of contrast, engineering shows an overall growth of between 2.6 and 4.5 per cent with aeronautical/astronautical employment rising by a massive 5.9–11.1 per cent per year, a gain of 22,000–45,000 jobs. Electronics is the other major growth occupation, and although it shows rather less spectacular growth of between 3.9 and 5.1 per cent, the expected gains of between 69,000 and 94,000 jobs match the absolute growth in jobs for computer systems analysts.

As well as considering possible demand, NSF also makes corresponding supply projections, taking account of such factors as new entrants to the labour force, occupational mobility, immigration, and deaths and retirements. The model projects that supply will exceed demand under all the scenarios for all science occupations; for example, there could be three people seeking every job. However, significant shortages are indicated for aeronautical/astronautical engineers and electronic engineers, together with particularly large shortages in the computer speciality fields. These projections, however, assume no major forms of labour force adjustment such as increased salaries, reduced hiring standards, significant mobility from other occupations or increased immigration. One particular concern is the possibility that industry may be so attractive that the universities will be unable to attract enough talented people for research.

Labour market adjustments are expected to alleviate the likely level and impact of shortages in the above disciplines, and also mitigate the size of surpluses. But NSF's main concern is that the larger the adjustment needed, the greater the impact on and likely lowering of the quality of the workforce. This could induce productivity and quality losses in the short term, while hindering longer-term supply of skilled manpower if the academic sector cannot retain graduate students or its existing faculty. Already many specialists in information technology are leaving academic posts for industry. However, for many of those seeking a science-linked job, employment prospects are declining and may continue to deteriorate for the next few years. Occupational mobility and retraining will then become higher priorities for the individual seeking secure employment. ☐

Targets for future arms control

Before East-West talks on arms control resume, there is a strong case for an examination of what the two sides should be aiming at — even for an agreement on the subject.

PREDICTABLY, not much has been heard of arms control in the past few weeks. For all the importance rightly attaching to the question how best to reach an accommodation between the Soviet Union and the United States on the range of issues left suspended at Geneva a year ago, it was never likely that the US electorate would let the presidential election be determined by the answers of the different candidates. And there is a sense in which the indifference is well-placed. Even if a re-elected President Reagan should be discovered to be more flexible than he has sometimes seemed to be, as on issues such as negotiation from strength, everybody knows that it takes two to make an equitable agreement — and nobody knows what the putative partners in negotiation are now thinking. But a new president, whatever his virtues, would be no more able to conjure agreement out of thin air, and would in any case have to spend time learning what kind of agreement would be acceptable. So what can people, in the United States and elsewhere, hope to be doing while waiting for the dust to settle?

The simple but important task that needs to be taken up is that of defining a stable and possibly attainable goal for arms controllers in the medium term, say by the end of the century. Such an exercise is not as academic as it seems, for there is a sense in which proposals for new arms control agreements between the Occidental super-powers or within larger groupings, reasonable enough in themselves, turn out to be insubstantial when set against the pattern of changing military technology and the complexity of the world in which international conflicts of interest must be supposed to continue to exist. This is the spirit in which the notion of a comprehensive ban on nuclear testing, desirable (and nearly attainable) in the early 1960s, would no longer be safe (on its own), let alone feasible. Similarly, because the Salt agreements (both I and II, the latter and the more important never ratified) say nothing about missiles of intermediate range, strategists have been stuffing Europe with SS-20, Pershing and cruise missiles.

These disheartening developments are not as surprising as they appear. This side of that utopian state of affairs in which international conflicts of interest have been subsumed in universal sweetness and light, no single arms control agreement of the kinds now talked about at negotiations can on its own be stable. A comprehensive test-ban treaty would survive only until one of the participants considered its position had been undermined by the development of other military technologies than those for bomb construction. The Non-Proliferation Treaty, which mercifully still holds, would not have much value if it were not backed up by a whole array of political restraints on potential bomb-makers, but would not last long if more than one or two of its signatories defected. Nuclear-free zones in Europe would probably survive for as long as the countries directly concerned agreed not to change their external relationships significantly. And even the design of a more general package of arms control measures to limit the damage that the superpowers may inflict on themselves (and others) requires, for stability, a clear understanding of what political changes will be allowed without bringing the whole agreement tumbling down.

Put directly, the problem is this. Is there any arms control regime that can be expected in Europe to survive, say, the transfer of one Central European state from one alliance to its opponent? As a corollary, is it possible to conceive of a regime for nuclear arms control in Europe that will allow conventional wars to proceed conventionally? And if not, what understandings about political change must accompany what the arms controllers agree? These important questions have been given far less attention than they deserve.

But do not the Helsinki agreements (on European security) serve just such a purpose? They formally require of signatory governments such liberality in regulation of people's freedom that, if the agreements were enforced, many potential international conflicts would never surface. The trouble, as the world knows, is that the Helsinki agreements are a dead letter, especially in Eastern Europe. But an attempt to breathe new life into them, perhaps by new administrations in the United States and the Soviet Union, would not be a waste of time.

The safest assumption (which some would think wild) is that Helsinki could yield, by 2000, an understanding that moderately paced political change would be permitted among the lesser allies of major powers, perhaps against a background of steady economic improvement (also one of the Helsinki objectives). Whatever the permissible pace of change agreed, it is unthinkable that either side would agree to the entire abandonment of nuclear weapons within Europe, while even some European states (France, for example) would think twice on that subject. The best realistic bet is that great-power deterrence would persist, but preferably based on relatively invulnerable submarines, and that nuclear warheads actually based in Europe would be limited to, say, a score on each side. Inspection and verification could be by means of human inspectors (one per warhead) and by tight control of military nuclear explosives. Such a force of warheads would have the limited purpose of helping defence against overwhelming conventional attack, and of alerting allies.

In such a setting, chemical weapons (more attractive to the generals as weapons in conventional wars) could and should be outlawed, while the regulation of nuclear facilities within Europe could obviously be enormously simplified. For the intercontinental powers, the accompaniment of this regime would plainly be such a tight restriction of strategic warheads — say 100 — that only bases in invulnerable submarines would make sense. In such a regime, it would obviously be sensible to aim at a cut-off of military production — no skin off the noses of the major powers but a help against proliferation. There are two views of this prospect — one that it is a cowardly over-modest goal at which to aim, the other that it is idealistically ambitious. The second opinion, unfortunately, is nearer the truth. □

New academic tests

British universities have to share funds for research. Self-choice is best.

BRITISH universities seem to have embarked on their new academic year in a mood blended of resignation and combativeness. After several years of shrinking budgets, and after a summer filled with threats that there is worse to come, even the hope of a period of stagnation, called "level funding" in the trade, seems almost too much to ask for. But, since the appearance of the University Grants Committee strategy document a few weeks ago (*Nature* 20 September, p. 193) some university administrators and their academic colleagues have indulged the fancy that the government is about to relent. What has happened is simply that the grants committee has taken a more robust view than in recent years of the universities' problems, and declared itself sympathetic to their needs. Specifically, it has made it plain that it does not passively accept that the universities can bend ever more pliantly to the government's demands (to train more engineers, for example) on a fixed budget. But as the experience of recent years has shown, even the strongest case may not prevail against a government strapped for cash. Lord Flowers, chairman of the Committee of Vice-Chancellors and Principals, was right to remind his constituents a week ago that this is not a "battle won, but a battle joined".

Euphoria is contagious, but dangerous. The debate arranged for 25 October in the House of Commons, on which many hopes are pinned, is almost certain to be a disappointment for the universities. Having lost their political friends in the 1970s, they are unlikely to be much comforted if the government's political opponents seize on what has been done to them as yet another stick with which to beat the administration over the head; or if, as seems likely, the government disarms criticism of its handling of British higher education in the past five years by a show of generosity, perhaps by promising an increase of the budget for university equipment. The test that those in higher education should apply to what is said in the House of Commons is that of whether the debate reveals an understanding that higher education (not just in universities) is a national resource and an economic and social necessity, not just a way of insulating a bunch of academic layabouts from the rigours of the labour market. (Tenure irrationally remains everybody's *bête noire*.)

Meanwhile, the universities have work of their own to do. The grants committee's document is rhetorically encouraging but full of pitfalls for the unwary or the indolent. Thus nothing substantial is said about the chief iniquity of the past three years — the imposition of student quotas that individual universities might exceed only at the risk of being penalized financially. The inference is that the grants committee will not in future enforce the rules its predecessor committee promulgated, which is a welcome development. The result should be that many universities will be able to make more economical use of the resources at their disposal by allowing departments starved of students to operate at full capacity. The snag, also only implicit in what the grants committee says, is that individual institutions will find themselves engaged in a complicated attempt to second-guess the grants committee. Taking in more students may help financially, if only at the margin, but may hazard an institution's capacity to compete for research support in future, but under a set of rules that has yet to be defined.

The issue is complicated and potentially contentious. The grants committee acknowledges, perhaps even overestimates, the importance of its financial support to the conduct of academic research in Britain. And now, when it is generally agreed that the dual mechanism of research support (from the committee and, in parallel, by means of project grants from research councils) has broken down, the committee says that it will in future be more discriminating between universities. All that makes sense, if only because, on paper, the present system provides all institutions with the general support that should enable them to compete for project grants in circumstances in which it is also generally understood that some are more able to compete successfully than others. Indeed, the grants committee has, over the years, implicitly trimmed its sails to this wind by being more generous to some universities than others while declining to say why, no doubt in the knowledge of the ructions there would be if universities had grounds for thinking that research support was being "earmarked", a synonym for the act of telling universities what to do and thus a gross intrusion into academic freedom.

So by what criteria will the grants committee discriminate among British universities in the provision of research support? By all accounts, the question has not been settled. All that the committee has said in public is that it will devise criteria that are distinct from those followed by the research councils in their provision of (mostly) project grants. Obviously that makes sense, for otherwise it would be just as well to replace the research councils as a whole by the grants committee. But what other yardsticks than peer-review, and a general sense of "timeliness and promise", can there be?

Here is one interesting and subversive way in which the grants committee might choose to solve the problem it has set itself. Why not, to begin with, take universities' own estimation of the reasons why they deserve research support? At first, the result would be that universities would share the research component of the grants committee's budget in much the same proportions as at present, and so might be tempted to assume that nothing had changed. But in making a case for research support, the prudent among them would be compelled to explain why their research proposals should be taken seriously. And the consequences of that could be enlivening. For it would turn out that universities that were capable internally of discriminating between good and less good research would be more likely to succeed in the second round of the proposed competition. And those which had the flair to spot new lines of promising research at an early stage, and the willingness to commit internal resources to their support, would be found to emerge with extra kudos from such competitions. So, properly handled, the grants committee's ambition to devise alternative criteria for assessing research support may turn out to provide two of the benefits conspicuous by their absence in recent years from the British system — internal mechanisms for deciding what backing should be given to what research, and opportunities by which institutions can improve their standing by their own wit. That such a system would also lend substance to the notion that universities are autonomous institutions even in the uncomfortable sense of that word is not the least of its attractions. □

Irish disunity

Bombs apart, Anglo-Irish talks are hopeful. Education deserves attention.

THE unsuccessful attempt to assassinate the British cabinet last week will have one important and beneficent consequence — that of further stimulating the search for an accommodation between the governments of Ireland and the United Kingdom over the Ulster problem. By all accounts, the weeks preceding the bombing of the Brighton hotel in which four people were killed were cheerful times for the officials labouring on the details of an agreement. What seems to have happened, on the British side, is that one minister, Mr James Prior, has been replaced (at his own request) by another, Mr Douglas Hurd. In the nature of this, the most disheartening job in British politics, new policies require new men, who usually have only one chance at a solution. Mr Prior's chief initiative, the consultation between Irish politicians called a forum, was less successful than it might have been because of the absence of the Ulster nationalists and the intransigence of the Irish nationalists. Within the same framework, Mr Hurd appears to be putting his energy into the building of common institutions, the touchstone of Irish hopes two years ago.

While it is remarkable (but unremarked) that many Irish institutions (rugby football and the administration of lighthouses, for example) have survived Irish partition, it tends to be forgotten that Irish higher education has preserved many of the appearances of commonality. As European citizens, Irish students can enter British universities without paying the penal fees exacted from other foreigners, but the Irish Government will not help with maintenance costs. Roman Catholic students from Ulster tend to seek higher education south of the border, when they are welcomed as if Irish. There is the basis for a deal between the two governments on this trade in young people's aspirations, as well as for an understanding that, for the purposes of research, the two countries should count as one. That should be at least one part of the package of proposals Mr Hurd is hoping to have assembled by next month. □

Fast reactors

Japanese plans delayed despite Clinch River bonus

Tokyo

JAPAN'S fast breeder reactor (FBR) research programme is running into financial difficulties, despite the recent gift of Y200-million-worth of unwanted research equipment and instruments from the US Government's abandoned Clinch River project.

The difficulties are caused by a massive increase in estimates of the construction costs for Monju, a 300-MW sodium-cooled prototype FBR to be constructed near Tsuruga in Fukui Prefecture. Monju is the key project in the FBR development programme and a major step forward from the 100-MW experimental reactor Joyu, which went critical in 1977.

Ground clearance operations have begun at the Monju site after several years of geological and seismic surveys. But construction costs have now risen from the 1980 estimate of Y400,000 million (US$1,600 million) to around Y590,000 million ($2,500 million). Responsibility for the project rests with the Power Reactor and Nuclear Fuel Development Corporation, a large research organization attached to the Science and Technology Agency. Funds for the project are not, however, entirely provided by the government, around 20 per cent coming, under a 1980 agreement, from privately-owned electricity utilities, largely through a power source development tax.

Now, the Science and Technology Agency wants to pass on a third of the extra costs to the utilities. They, however, have refused point blank to increase their contribution, arguing that any further funds could be found only by increasing electricity charges — something the government is anxious to avoid.

The shortage of funds is likely to hit the project hard next year when construction should move into top gear so as to finish by 1990. At present, given that the Japanese Government is already running an enormous budget deficit, the most likely option is to postpone the completion date by up to 5 years and to slow down the rate of construction to match availability of funds.

The pessimism over completing Monju on time comes just as the federation of electric power companies and the big five nuclear construction companies have launched a new Y6,000 million ($25 million) study project to choose the basic design for Monju's successor, a 1,000-MW demonstration reactor expected to be ready by the end of the century. The three-year study will aim to make the choice between a loop type design, in which heat from the primary sodium coolant is transferred to a secondary liquid sodium system outside the reactor, and a tank type in which the heat exchanger is located inside the reactor. The two reactor types are being researched by groups led by Mitsubishi and Hitachi–Toshiba respectively.

The key to success is to find some way to cut the enormous construction costs of the FBR, currently estimated at around two and a half times that of a conventional light water reactor. One way in which this will be tackled is through a joint US–Japanese project, agreed in principle this week, to perfect methods of driving the sodium coolant by electromagnetic forces rather than by a conventional pump.

Technical specifications for the reactor are to be examined by the French company Novatome, for although enthusiasm for FBRs remains great in Japan, the technology is still a long way behind that of France. The French began operation of a 250-MW prototype FBR, the Phénix, in 1972 (at the same time as a similar reactor at Dounreay in the United Kingdom) and expect to have Super-Phénix — the world's first demonstration FBR — ready by 1985, some 15 years ahead of any Japanese competitor.

Alun Anderson

Danish physics

Niels Bohr on a shoestring

Copenhagen

THE Niels Bohr Institute for nuclear and particle physics in Copenhagen, which celebrates the centenary of Bohr's birth next year, is in dire straits because of opposition to nuclear power in Denmark. That, at least is the opinion of one of its professors, nuclear theorist Aage Winther. For the result is poor student enrolment in physics at the University of Copenhagen (of which the Niels Bohr Institute is a part), and some departments with five physics lecturers per student. Because university research funds are distributed in rough proportion to student numbers, these are hard times for the Bohr Institute.

There have been no new research posts at the institute for seven years. With a staff of 50, the institute needs one or two posts a year to keep alive, Winther reckons. A clutch of retirements begins in five years' time, but meanwhile, the institute needs perhaps 10–15 new staff. Will it happen? Winther throws up his hands in a gesture of doubt. Sad news for a city that gave its name to the statistical interprepation of quantum mechanics and for the institute that housed Europe's first cyclotron. The Niels Bohr also began the European Organization for Nuclear Research (CERN), now based near Geneva, as a theoretical group in 1951.

The trouble lies not only with the opposition of the young to things nuclear and the fashion (as Winther describes it) for the new biology. The Danish university system, in which the Niels Bohr is enmeshed, is in something of a mess. First degrees typically take 8–10 years to complete, with some students stretching out their time to the age of 34. After such a long first degree, there are very few postgraduate students.

Also, as in many countries, research funds have been pared down "to the level of counting pencils and erasers". The goverment expected the universities to perform major surgery on themselves, says Winther. "But how can we do that with our democratic structures?" All university committees have 25 per cent representation from students and 25 per cent from technicians, says Professor Teder Olesen Larsen, chairman of the national science policy advisory committee. "With such a broad structure the only decisions the universities can take are decisions to do nothing."

Thus the Niels Bohr Institute and many other important laboratories in Denmark's universities, have been submerged — except where they can fight for special support. This is often distributed by the government in "cigar boxes", a Danish phrase for special-purpose funds administered separately from the 10 per cent or so of research money that comes through the Danish research council system. Thus when essential moneys were allocated for the re-instrumentation of Danish laboratories, the money came from a "cigar box", where research council priorities were not easy to take into account. With so many special funds, the Danish research support system has now become "Kafkaesque", says Olesen Larsen.

The Niels Bohr is hoping to insulate itself from these problems in two ways. First it has negotiated a deal with the government that will give it more funds than its low student intake would normally entail. But the money will go in a lump to the university administration, and it is yet to be seen whether it comes the institute's way, says a cynical Winther. But as a second string, the Niels Bohr is hoping to raise more external support — which, with 50 mostly foreign visiting scientists, is already large. "We hope to make a success of our 100th anniversary celebration next year", says Winther, "by appealing to our external benefactors". Among them have been the US Ford Foundation and National Science Foundation; the Nishima Foundation of Japan; and the Italian national institute for nuclear physics (INFN). They should expect a few discreet Danish knocks on their doors next year.

Robert Walgate

European biotechnology

Community seeks new funds

Copenhagen

THE Governments of Austria, Switzerland and Sweden have asked the European Commission if they may join in the European Economic Community's next biotechnology programme, even though none of them belongs. The decision rests with the European Council of Ministers but the signs are that the applicants will be refused.

If so, this would be an inauspicious start to the 154-million-ECU (£130 million) five-year programme, which has as yet not an ECU (European currency unit) to call its own. The research plan, called the "Research Action Programme" (RAP) in biotechnology, has been conceived as a development and sixfold amplification of an existing Community biotechnology programme devoted to agriculture and food, the "Biomolecular Engineering Programme" (BEP). BEP has had "a tremendous impact" on developing collaboration among European research groups in plant sciences, said one senior participant speaking at a meeting last week to take stock of the programme.

Others, however, claim that while BEP has certainly been good for Europe, its benefits — new collaborations — will fade away when BEP ends (in March 1986) unless new funds are found to pay the costs of travel, meetings, training and materials now supported under BEP. Participants point to an earlier successful programme on photosynthesis, which collapsed when the programme finished.

One of the successes claimed for BEP last week is that work on the mitochondrial DNA of plants is now more advanced in Europe than elsewhere, partly as a result of the collaborations that have been supported. Without claiming sole credit, officials were gratified last week to hear from Professor Jeff Schell and his colleague Professor Marc van Montagu that *Agrobacterium* plasmids can be cloned into a monocotyledonous plant, *Asparagus officianalis*.

It seems to be agreed that BEP is responsible for the stimulation of *Agrobacterium* research in Europe and for establishing joint research programmes between groups that would otherwise have been working independently and in duplication. "The money has been better spent than it would have been in separate national programmes", said one participant.

BEP and, by extension, its successor, is not, however, without critics. Professor Schell, of Cologne and Ghent, doyen of the *Agrobacterium* vector for introducing foreign genes into plants, considered that the funds available (15 million ECU from Brussels) have been too thinly spread, but fears that if there were a massive increase in the budget, the money might be wasted among the undeserving masses.

Commission officials say, however, that the objectives of the new programme are different, and that in the plant sciences, the best groups and programmes have already been identified. RAP would develop the programme, but also support initiatives in bioreactor technology (in particular for multi-enzyme, multi-phase and co-factor-requiring reactions), vaccines, hormones, gene transfer in animals, microbiology, the methodology of animal cell cultures (for monoclonal antibodies), new methods for toxicological testing and other fields of "basic, pre-competitive" research.

Whether funds for the new programme will materialize is, however, still an open question. France, West Germany and the United Kingdom are objecting to the cost, even though all governments gave outline approval last April. Now the European Commission is trying to persuade ministers to open their purses by quoting the poor opinion of European biotechnology expressed by the US congressional Office of Technology Assessment, published in January this year (see *Nature* **307**, 402; 1984).

Robert Walgate

Danish collaboration

Europe seems long way south

Copenhagen

THE Danish minister for education and science, Mr Bertel Haarder, is to make a strong protest at the next European council of research ministers at the way in which France and Germany appear to have decided between themselves where to put the proposed European Synchrotron Radiation Source (see *Nature* 4 October, p.399), trading a trans-sonic wind tunnel for Cologne against the ESRS for Strasbourg or Grenoble.

Denmark had offered to site ESRS at the Risø atomic research centre, and had offered DKr 350 million (£25 million) to help pay for it. But now Denmark feels its proposal was not properly assessed.

"We are very very upset", said Professor Teder Olesen Larsen, chairman of the Danish advisory council for science policy, last week. As well as Haarder's protest in Brussels, Denmark is to raise the issue at the annual general meeting of the European Science Foundation (ESF) in Strasbourg in November.

The ESRS project has been managed by ESF since 1979, and site proposals should have been assessed and compared by an ESF technical committee. In Denmark, it is now felt that this scientific assessment never took place, or at least was not taken seriously. A detailed Risø proposal has still not received a reply said Olesen Larsen.

The Risø proposal is generally believed in Denmark to have been technically excellent, and to have had a good chance of success if purely scientific criteria had been involved. "We would be very disappointed if a decision was reached by Franco-German agreement", said Olesen Larsen. "We are not going to be dictated to in that way." The French research minister, Hubert Curien "has a responsibility" at the very least to put the Franco-German proposal before the ESRS technical committee. If nothing is done to heal wounds there could be "very strong and nearly disastrous consequences for ESF", Olesen Larsen said.

According to Professor Alan Mackintosh, an ex-director of Risø now at the University of Copenhagen, Denmark has a good record in synchrotron radiation research. Indeed, the latest design of ESRS was coordinated by a Dane, Professor Bronislav Buras, at the European Organization for Nuclear Research (CERN) near Geneva. The Nordic countries are also dismayed that they have never had a major European research facility (except the ionospheric laboratory, EISCAT). The complainants are, however, more reticent about the urgent domestic case for Risø as a site. It is one of those big laboratories originally devoted to nuclear research that needs to find new goals. ESRS would have suited it very nicely.

Risø's problems have been sharpened by the tacit Danish Government decision to abandon all hope of developing nuclear power stations in the light of the recent vote by the Social Democratic Party (SDP) (now opposing the centre-right coalition government) against nuclear power. Taking SDP together with the centre ("Radical") party, there is probably now a majority in the Danish Parliament against all nuclear development. For the first time in years, the Danish Prime Minister failed to refer to a nuclear future for Denmark in the opening speech to Parliament this month.

Another question-mark to place against Danish interest in ESRS could be the Danish commitment to another European institution, the European Molecular Biology Laboratory (EMBL) at Heidelberg. Denmark has kept its continued membership of EMBL in doubt now for three years — and that doubt will continue if Olesen Larsen's science policy committee has its way. A committee of biologists had recommended in August that Denmark should finally announce its long-term confidence in and commitment to EMBL, which costs the country DKr 3 million (£210,000) a year; but the committee has rejected that advice, and instead advised Minister Haarder to leave the matter open for another three years — and meanwhile encourage more Danish molecular biologists to use the laboratory. Haarder has yet to decide which advice to take.

Robert Walgate

Japanese conservation

Aphrodisiacs and whales excepted

Tokyo

PRINCE Philip, Duke of Edinburgh, visiting Tokyo in his capacity as president of the World Wildlife Fund, has called upon Japan to take more vigorous action to abide by the Washington Convention — which regulates international trade in endangered species. His comments add to savage criticism of Japan's disregard of threatened species voiced at last week's Asian Pacific regional meeting of the convention — and comes when the Japanese Government is in a quandary over what to do about the cuts in whaling quotas agreed earlier this year by the International Whaling Commission (IWC).

The regional meeting of the convention on international trade in endangered species, held in Kuala Lumpur, ended with the adoption of a resolution severely criticizing Japan for failing to enforce the convention, which permits trading in endangered species only when official permission has been given by both exporting and importing countries. Japan is one of the signatories but has never actually enforced the regulations properly.

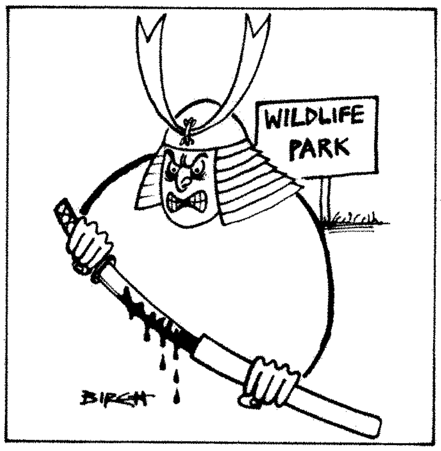
Critics at Kuala Lumpur pointed out that, despite the great efficiency with which Japan controls the import of manufactured goods, no experts are provided at customs offices who can check the status of a species or the validity of documents showing where animals have come from. The result is that Japanese traders have found it easy to deal in a range of endangered species — in a recent case, it was found that extremely rare lion tamarins (*Leontopithecus rosalia*) had been brought from Brazil with forged permits — as well as being able to sell large quantities of ivory, furs and tropical fish.

On top of lax adminstration of existing regulations, the Japanese Government has excluded from control 14 species recognized as endangered by the convention on the grounds that they are "vital for domestic industry". Chief among the excluded species is the musk deer, which has now been exterminated in most of India and is found in only a few isolated areas of the Himalayan states of Nepal, Sikkim and Bhutan.

Despite the real risk of extinction, the enormous prices that Japanese dealers will pay for the male deers' musk gland meant that around 3,500 adult male deer were killed last year. Probably four times that number of deer died when the young animals and females that fall into poachers' traps are included. All this to supply the ingredients for a traditional Chinese medicine of very doubtful efficacy.

The Kuala Lumpur meeting's resolution is not on its own expected to have much influence; it had been expected and discounted in advance by the Japanese. A representative was sent only to the first day of the two-week meeting. Later, financial restrictions were claimed to have prevented fuller attendance. Of the other 16 Asian-Pacific member countries, only Iran was absent.

Prince Philip, on his visit to Japan, also said he tended to the pessimistic view that whale stocks are declining rather than the optimistic view, taken by the Japanese, that commercial whaling can be continued without pause, and he argued that continued Japanese hunting of sperm whales would run "counter to the world consensus of opinion".



But the Japanese Government has already decided to permit sperm whale hunting in Japan's coastal waters on the grounds that it is a domestic matter. And, last week, the decision was made "in principle" to join the Soviet Union and Brazil in objecting to the cut in the minke whale quota agreed at the IWC meeting earlier this year (see *Nature* **310**, 440; 1984). The objection will not, however, actually be lodged, and Japan will not actually break the quota agreement, until all attempts have been made to persuade the US Government not to retaliate by cutting fish quotas in US waters, as the United States has said it will do to any country disregarding IWC agreements.

A decision is unlikely to be reached until after the US presidential election in November. Right now, anyway, fisheries agreements are not a popular topic in Japan. Not only are talks with the Soviet Union over salmon fisheries stalled, but Japan has just been accused of systematic violation of US fishery quotas in the North Pacific region. The Alaskan office of the US Department of Commerce's National Oceanic and Atmospheric Administration has claimed that the Japanese fishing fleet has been deliberately misleading US observers placed on-board fishing boats and has been using secret telegraph codes to broadcast the presence of patrol boats.

It is expected that Prince Philip will raise conservation issues when he meets Prime Minister Yasohiro Nakasone later this week.

US patents

Dying Congress aids innovation

Washington

THE 98th United States Congress ground to an inglorious halt last Friday after a frantic series of eleventh-hour compromises between the House of Representatives and the Senate that still left several major items of legislation unfinished and hence abandoned. Drafters worked around the clock, and such was the confusion that military jets had to be used to ferry back to Washington senators who, keen to start campaigning in their home states, had left the capital before a final vital vote authorizing next year's budget deficit.

Among last week's casualties were the Export Administration Act, which might have established a new framework for the control of high-technology exports but which resisted last-ditch efforts to reconcile House and Senate views, and the controversial Simpson–Mazzoli immigration bill.

But there were also successes. Manufacturers of "generic" pharmaceuticals won a last-minute battle in the Senate to strike out a section of the 1984 Patent Law Amendments Act that would have extended the scope of US process patents to cover products made outside the United States. At present, there is no straightforward way in US law (in contrast with the position in Europe) to prevent a "copycat" manufacturer from using a home-patented process abroad and then importing the end product for sale. As first drafted, the bill would have put a stop to that, but the generic manufacturers argued successfully that they would be prevented from conducting safety tests for their products if foreign suppliers were unwilling to testify before US courts about their manufacturing processes.

The bill as approved does, however, include measures to help inventors working in companies or universities. A new device, the Statutory Invention Registration (SIR), will enable an inventor to stake his claim for patent rights at little cost and without a full patent examination. An SIR would become "prior art", thus preventing a patent claim by a later inventor, and could be upgraded to a full patent later.

Another provision in the bill would alter the definition of prior art to exclude private communications between members of a research team, thus making it easier for team members to claim patent rights. Inventors will not have to work together to be able to claim joint inventorship, and different claims made by different inventors will all be entitled to the benefits of the earliest filing date. The bill would also establish a national commission on innovation and productivity to examine inventors' rights in relation to their employers.

Tim Beardsley

Soviet astronomy

Astrophysics in space

FRANCE is to build a 1-tonne gamma-ray telescope and imaging system to be launched by the Soviet Union aboard an Astron satellite in 1987. The project, which has been under discussion for some time, is covered by a special protocol signed earlier this month in Samarkand during the regular annual meeting of the Franco-Soviet working group on cooperation in space.

The announcement from Samarkand suggests that the name Astron, at present denoting the astrophysical satellite launched on 23 March 1983, is to become the name of a series. The first is basically a Venera-15 backup, stripped of its navigation gear and course-correction motor. The satellite carries an optical telescope (the largest to be orbited so far), an ultraviolet telescope, a spectrometer (produced by the Marseilles laboratory of space astronomy) working in the 1,100 to 3,500 Å range and an X-ray telescope-spectrometer in the 6 to 0.5 Å range. A high apogee (200,000 km) orbit is used to eliminate interference from the Earth's radiation belt and corona.

French participation in Astron-1 is confined to the X-ray study of normal stars and extended surfaces. The more spectacular results have, however, come from the Soviet part of the programme although — in the case of the anomalous behaviour of the X-1 Hercules X-ray signal — the observations were confirmed by the European Exosat satellite. X-1 Herculis is a double star consisting of the visible HZ-Herculis and a neutron star (the X-ray source). In the course of an observation session on 30 July 1983, the X-ray signal was found to have vanished, although visual observations from the Byurakan and Crimean observatories found no significant changes in the optical brightness curve. This suggested that the loss of signal was due to some change in the accretion disc of the neutron star, possibly in the angular distribution of the radiation. During a subsequent observation session on 1 March 1984, the signal was found to be back to normal.

Other surprises have included the anomalous spectrum of 73 Draconis (in which the content of heavy elements (lead, tungsten and uranium) was considerably higher than theoretical predictions and the ultraviolet observations of the double stars SS-Auriga and SS-Andromeda, which indicated that the "hot" components have dimensions only a few per cent of the radius of the Sun. Also unexpected were the results of the occlusion of "fast burster" MXB 1728-34 by the Moon on 16 August, 1983, which suggested that, during the occlusion, the source had emitted constant X-radiation, not the expected sequence of discrete pulses.

Astron is a major research project, involving a number of high-level Soviet institutes. It is therefore not surprising that these results have been given wide publicity in the general Soviet press, which claims every result as a major breakthrough. One newspaper even suggested that the work on 73 Draconis would lead to a greater understanding of the origin of metals.

It is also surprising that there are frequent errors in these popular reports. Thus the "hot" components of SS-Andromeda and SS-Auriga were said to have a temperature of 100,000K (not 60,000K), the lead and tungsten content of 73 Draconis have been described as "100,000 times higher than in the Solar System" and, on one occasion, TASS distinguished itself by locating the Astron telescope not in orbit but at the Byurakan observatory in Armenia. **Vera Rich**

US health research

NIH further subdivided

Washington

CONGRESS last week approved a controversial research extension act for the National Institutes of Health (NIH) that creates three new institutes and for the first time sets out policy and general research directives for NIH component institutes. The bill was passed in the face of stiff opposition from NIH, which wanted to retain their existing freedom to set their own research priorities. The director of NIH, Dr James Wyngaarden, fears that the creation of new institutes will only add to bureaucracy and said that NIH will have to "find ways of accommodating" to the bill.

The principal change is the splitting of the National Institute for Arthritis, Diabetes, Digestive and Kidney Diseases into a new National Institute of Arthritis and Musculoskeletal and Skin Diseases and a separate National Institute for Diabetes, Digestion and Kidney Diseases. Part of the reason for the split appears to be the wish of private fund-raising organizations to have their favourite diseases incorporated into the name of an NIH institute. In addition, Congress has voted to create a new National Institute of Nursing: as politicians, congressmen are doubtless aware that few things are so likely to endear them to their electorates as the creation of a new medical institute.

Wyngaarden says the new institutes will create administrative costs without significantly benefiting the target areas: the work proposed for the new arthritis institute, costing $80–100 million a year, is currently being carried out by the existing parent institute. The new act contains no special authorization for new bureaucratic costs. And the proposed research in nursing could best be done through existing mechanisms, according to Wyngaarden. But whatever the frustrations of a Congress that likes to involve itself in research administration, the ever-popular NIH have little to complain about on budget; this year Congress has allocated $5,000 million to NIH, a hefty increase on last year and way above the administration's request. But Congress does seem concerned about the threat of charlatanism. The legislation approved last week formalized for the first time the need for peer review of NIH research contracts and grants, and also requires administrators to set up mechanisms for investigating "substantial" scientific fraud. **Tim Beardsley**

Health ethics

THE House and Senate also agreed last week to establish a Congressional Ethics Advisory Commission to study human genetic engineering and fetal research. The commission, to be modelled on Congress's Office of Technology Assessment, will report on scientific developments to Congress and the public, supported by a 14-strong biomedical ethics advisory committee.

The commission is seen as the US answer to the Warnock Committee in Britain, although it is expected to be more permanent.

Two studies are specifically mandated: whether the stringent federal protections for fetuses are appropriate for research, and the ethical implications of developments in genetic engineering technology that might be applied to humans.

As things stand, NIH are in practice barred from supporting research on *in vitro* fertilization and embryo transfer, and right-to-life ideologues in the administration who ally themselves to the Moral Majority are content to see things stay that way. The creation of the new commission is seen by its supporters as a vital first step towards new policy development.

Tim Beardsley

Acid rain

Parliament in power row

AN almost unprecedented row about acid rain has broken out between the Central Electricity Generating Board (CEGB), the monopoly generator of electricity in England and Wales, and the House of Commons Select Committee on Energy. The board's chairman, Sir Walter Marshall, last week complained that the select committee had "unfairly" pilloried his organization in a report on acid rain published a month ago (*Nature* 13 September, p. 94).

The House of Commons report differs from others on the subject including that earlier this year from the House of Lords, in the directness of its attack on CEGB, which is at one point accused of "ignorance or a deliberate attempt to mislead". That comment was the committee's response to CEGB's argument that forest damage in West Germany is now thought to be caused by ozone, whose formation in the troposphere is stimulated by nitrogen oxides in the presence of sunlight.

Readers of the published report are likely, on reflection, to agree with Marshall that CEGB has been misunderstood, while it also seems that the committee's complaint at the supposed inadequacy of the board's research programme does not assign proper credit for what is being done. Apart from basic research, its board is supporting studies of combustion systems intended to bring reductions of acid emissions of all chemical compositions.

Marshall last week repeated CEGB's position on the steps that could be taken to reduce emissions of sulphur dioxide, saying that "if reducing CEGB sulphur dioxide emissions would solve real environmental problems in the most cost-effective way, we will get on with the job despite the costs". He quoted estimates that the retro-fitting of flue-gas desulphurizing plant to a large generating station might cost £140 million.

According to Marshall's statement last week, the problem of control of nitrogen oxides (NO_x) is different and more difficult. Combustion systems designed to increase thermal efficiency by burning combustible material close to boiler walls will actually increase the production of NO_x, for which reason such a boiler fitted with specially designed burners is to be put in trials beginning in 1986. But CEGB is also planning to carry out trials with a corner-boiler at its Fiddler's Ferry power station. Each experiment will cost about £2 million.

The outcome of the dispute between the nationalized industry and the House of Commons committee is hard to predict. Although the committee seems in part to have reflected a general opinion that "something should be done", it is the British Government and the European Commission that will eventually determine policy.

Marshall himself, who was made a freeman of the City of London last week, is unlikely to be accused of a breach of parliamentary privilege, even though it is customary for people in his position to leave their defence to the appropriate government department. ☐

Health advice

Berkeley goes into business

Los Angeles

DEAR SUBSCRIBER ELECT,

AND NOW THERE IS, AT LAST, AN AUTHORITATIVE NEWSLETTER DEALING WITH THE SUBJECT OF HEALTH AND NUTRITION THAT IS DESIGNED TO KEEP YOU WELL AND MAKE YOU MORE WELL. HOW AUTHORITATIVE? AS AUTHORITATIVE AS THE UNIVERSITY OF CALIFORNIA, BERKELEY, SCHOOL OF PUBLIC HEALTH CAN MAKE IT.

So begins a solicitation recently mailed to two million households throughout the United States to pay $15 a year (soon to be $18) for yet another health publication. But this, according to its promoters, is different.

"Every last word" of each article is approved by the faculty of the Berkeley School of Public Health, says the school's dean, Joyce Lashoff. The faculty's goal in this unusual endeavour, Dr Lashoff says, is to "put current information about health and nutrition in perspective".

In so doing, the School of Public Health stands to make a substantial profit. "They'll do very well", says New York-based publisher Rodney Friedman, who first proposed the idea and raised the venture capital to launch the project. The contract says the school receives 5 per cent of all gross billings, which translates, with regular subscriptions at $18 per year, into $75,000 for every 100,000 subscriptions. The publishers' ultimate goal is to attract 250,000 subscribers, when the School of Public Health would earn more than $180,000 a year for giving its expert opinions and final editing to the newsletter. University of California budgets have suffered cutbacks in recent years, Mr Friedman said, and the public health school will be able to spend the money from its newsletter venture as it sees fit.

The United States market for health and nutrition news seems insatiable. Over 30 magazines and a dozen newsletters publish hundreds of articles each month on how to prevent, cure or cope with illness. Much of the information, according to a recent survey by the American Council on Science and Health, is poor if not dishonest.

The credibility of the Berkeley School of Public Health stands behind the newsletter, participants say. The eight-page publication, called the *Wellness Newsletter*, aims to give specific advice, written in a short, "palatable" format, on how to improve or enhance health.

A few other universities publish monthly health newsletters, but they are said to be disease-oriented and not written for a broad consumer audience. Nor do individual departments profit so directly from the endeavours. Other academic departments in other institutions may want to keep an eye on the California project as a model for increasing budgets to train graduate students and buy equipment, the objectives which the Berkeley School of Public Health has set itself for the disposal of the income it hopes the project will generate.

Sandra Blakeslee

Chip pirates hit

Washington

SEMICONDUCTOR chip manufacturers last week succeeded in their goal of protecting circuit designs against "chip piracy" — unauthorized sale and distribution of a copied device. Congress finally approved a bill that for the first time grants copyright protection for the masks used to manufacture semiconductor circuits.

The United States dominates the chip supply industry, a world market estimated to be worth $16,000 million a year in 1983. The manufacturers' complaint has been that a chip costing millions of dollars to develop can be copied photographically and "reverse engineered" for as little as $50,000, thus denying designers the incentive to innovate. US dominance of the industry has been achieved only through massive research and development efforts: in 1982, average research and development expenditure in the US semiconductor industry amounted to over 10 per cent of sales value, with capital investment over 14 per cent.

Circuit designs, however much careful work they represent, rarely meet the standards of inventiveness needed for patent protection. And, because chips are so easily copied, trade secrecy does not help either. The new bill, the Semiconductor Chip Protection Act, commanded widespread support in Congress and is likely to be signed into law very soon. It provides "mask works" (in whatever physical form) protection against unauthorized copying for 10 years. (Other copyright designs can be protected for up to 100 years.) The bill also breaks new ground in allowing copyright of a utilitarian design; in previous copyright law, only non-functional aspects of design have been covered, a change that appears to have troubled the Copyright Office. The impact on the semiconductor manufacturing industry will be immediate: chip piracy is already big business in some parts of the world.

Tim Beardsley

Israeli aid

Hidden cooperation revealed

Rehovot

AFTER a decade of discreet silence, Israel's programme of scientific and technical cooperation with developing nations has suddenly surfaced. Last month, the International Cooperation Department of the Foreign Ministry announced that Israel had hosted 28,000 trainees from developing countries between 1958 and 1983, and during that same period some 8,500 Israeli experts had worked overseas.

The programme really began in 1957, when Israel helped to create Ghana's Black Star Shipping Line and to organize Ghana's Trade Union Congress. In the years that followed, cooperation flourished on many levels.

During that period, Israel worked not only with national governments but even with some liberation movements, for example training nurses from underground groups in Mozambique and Angola. Although most developing countries cut off diplomatic relations with Israel after the Yom Kippur War in 1973, it now appears that cooperation has continued with most of them, but quietly.

The emphasis of these programmes has always been on agriculture, but experience has shown that transferring technical know-how is much easier than transferring social forms. The so-called "Rehovot Approach" to integrated rural planning, has, however, proved itself in many developing countries. The aim of this approach, taught so far to 1,000 students from 50 countries at the Rehovot Settlement Study Centre, is to make life in rural areas more attractive so as to stem the flood of country people to urban slums.

The seven-month course, four months of which are spent in Israel, concentrates on the creation of new jobs as well as of a network of economic, social and community services. Comprehensive plans have been prepared for the Lampang Region of Thailand, the Neru Region in central Kenya and several places in Latin America. One group of Israeli experts is now working in Fiji on plans for a multipurpose rural services centre and the development of rural cooperatives, in collaboration with no fewer than 20 Fijians who have studied in Israel.

In medicine, Israel no longer provides a full-scale six-year course in medicine for students from developing countries, but instead a one-year course in public health and an MA course in community medicine. Much of the effort is concentrated in ophthalmology, as the result of which a dozen African countries have advanced eye clinics. Feasibility studies are first carried out by Israeli physicians; local doctors and nurses are brought to Israel for specialized training and, finally, expatriate Israelis are seconded to this clinic for a couple of years.

As might be expected in a country with enormous financial problems, there are people in Israel who question the wisdom of spending money on cooperation with nations which often do not have diplomatic relations with Israel, and which regularly vote against Israel in the United Nations. Mr Johanan Bein, director of the Foreign Ministry's International Cooperation Department, is philosophical. He says that the total cost of the programme is not large and that more than half of Israel's costs are borne by other countries, mainly in Western Europe, which sub-contract work in fields such as arid-zone agriculture.

Bein also notes that a few African countries, including Zaire and Liberia, have recently re-established diplomatic relations, and that in others without formal links, such as Nigeria, the Ivory Coast and Ghana, Israeli companies are now involved in development programmes much larger than the Israeli Government could have mounted. There are also hopes of a further political payoff, illustrated by the fact that among the 13,000 students from 100 nations who have participated in labour studies programmes run by Israel's General Federation of Labour, there are now 37 secretary-generals of union federations, 300 chairmen or secretary-generals of individual unions, over 150 members of parliament and several dozen ministers, including three prime ministers.

Politics apart, there is also a sense of mission. Forty years ago, chemist Chaim Weizmann, due to become Israel's first president, was corresponding with Maung Kyi (deputy secretary of the Burmese National Planning Department) and with a number of Indians, including Jawaharlal Nehru, about possible scientific cooperation between the Jewish State on the one hand, and India and Burma on the other. Even at the lowest point in relations between Israel and the governments of developing countries in 1973, when most of her long-time friends had turned their backs on her, Golda Meir, then prime minister, said that political disagreements were "no excuse for disowning or belittling . . . an attempt on the part of one country to better human life in other countries". **Nechemia Meyers**

Israelis visiting China

Rehovot

AMBIGUITY continues to attend the status of Israelis making scientific visits to the People's Republic of China. So much is clear from the experience of Dr Smil Ruhman, professor at the Weizmann Institute, at the First International Conference on Computers and their Applications in Beijing this summer.

Although Ruhman was an invited speaker listed (with his affiliation) on the programme, he notes that Israel was not listed among the overseas countries participating in a report on the conference published in the *China Daily*. Technically, this may have been correct, because Ruhman entered China on a US passport, having dual nationality.

Others, such as Mordhay Avron, have been less fortunate. Invited by the organizers of the 11th International Seaweed Symposium to give a talk at Qingdao in June 1983, and listed in the official programme, Avron was told to apply for a visa in some country with which China has diplomatic relations. In the event, he was told by the Chinese Embassy in the United States that a visa could not be issued there and, eventually, by the conference organizer, Dr Tseng, that the invitation to speak was conditional on possession of a visa.

Ironically, Ruhman has returned from China brimming with enthusiasm for the opportunities for collaboration, in which, he says, Israel has some distinctive developments to offer the Chinese. He, like many others, hopes that Chinese policy on passports will change. Nechemia Meyers

Democratic elitism

CHINA, as part of its policy of reversing the anti-intellectual attitudes of the Cultural Revolution, has inaugurated a scheme of state awards for "the promotion of scientific and technological advances". State prizes for science are a feature of most socilist societies, but the Chineses regulations, promulgated last month, contain a unique feature — the decision of the adjudicators is not final.

According to the recommended procedure, the names of the winners chosen by a special examination committee must be published at least three months before the awards are conferred. Complaints against the winners may be lodged within that period. Such complaints will then be investigated by "appraisal units", who will then report back to the examining committee for a final decision. If no complaints are sustained, the winners will receive their prizes.

There are three classes of award, each consisting of a citation and medal together with a sum of money (15,000 yuan — £5,000 — for a first class award, down to 5,000 yuan for a third class). Provision is also made for a "special-class" award, of greater (but unspecified) monetary value, for a "scientific and technological advance that makes special contributions to socialist modernization".

In the case of joint achievements, the cash is to be divided "rationally" according to the contributions of individual team members to the project, with those who made greater contributions getting the greater rewards. "It is impermissible", the regulations warn "to practise egalitarianism." • Vera Rich

In defence of CERN

SIR — May an observer well acquainted with US and European particle physics comment on the report of social scientists Ben Martin and John Irvine on the achievements of CERN, the European High Energy Laboratory in Geneva (*Nature* 6 September, p.4)? I find this report unfairly biased against CERN.

When European high-energy accelerator research on a large scale began in 1960, CERN was a completely novel social experiment. There was almost no tradition of "big science" in Europe, and no experience of international scientific management. Nevertheless, within less than 24 years, CERN had developed into the world's leading laboratory in this field.

Why then do Martin and Irvine consider CERN's performance disappointing? They concentrate their attention on sensational peak discoveries, in which respect CERN has contributed only in recent decades. But science does not consist of discoveries that make headlines in newspapers. The bulk of science consists of a broad front of painstaking investigations, leading to ever deeper insights. They are the soil from which striking discoveries can develop. In this respect, CERN has made many contributions to which Martin and Irvine give only passing attention.

It is true that some of the peak discoveries, in particular the so-called *c* (charm) and *b* (bottom) quarks, could have been found at the intersecting storage rings (ISR) at CERN. Other "sensational" discoveries, the violation of parity, the Ω-minus and the two types of neutrinos, which CERN is blamed for missing, were made in the United States before or at a time when research had barely started at CERN. But even if one insists on counting the lucky events of that type, CERN did not fare so badly during the second half of its research period. It discovered a new form of radioactivity, the so-called neutral currents, the well-advertised quanta of the weak interaction and probably a sixth quark (*t*, for top) as well.

Martin and Irvine ascribe the latest achievements to a recent change of spirit due to the present director. It is true that Herwig Schopper vigorously supported the last phases of the conversion of the super proton synchrotron (SPS) as a proton–antiproton collider, and the subsequent successful research. However, Martin and Irvine do not seem to appreciate that the conversion of an accelerator and the preparation of such giant experiments take much longer than the three and a half years of Schopper's directorship. The daring spirit and the technical inventiveness that have led to these achievements date from much earlier times. They are a proof of the opportunities given to individual scientists, which Martin and Irvine consider to have been too restricted at CERN. They also show a steady growth of this institution towards its present world supremacy, that started long ago.

The comparison with Fermilab in the United States is unfairly presented. True enough, several great discoveries were made at that laboratory, such as the existence of a fifth quark. But it was the CERN accelerator that was able to produce sharp and intense muon and neutrino beams with which the so-called structure functions of protons and neutrons were determined with astounding accuracy. Moreover, the important "EMC-effect" was discovered, which has led to a new view of the role of quarks in the atomic nucleus. One of the main purposes of those accelerators was the production of usable secondary muon and neutrino beams, in which CERN was much more successful than Fermilab inspite of the latter's four-year lead. Why do Martin and Irvine not appreciate these successes? Why do they consider them to be dull physics?

CERN's contributions to the physics of nuclear structure are almost completely neglected in Martin and Irvine's report. CERN has the most advanced isotope separation device (Isolde) attached to its synchro-cyclotron, where many new unstable nuclei have been discovered and studied. Recently, a low-energy source for antiprotons was constructed (LEAR) which provides unique opportunities for the study of antiproton interactions.

The success of CERN is based to a large extent upon a circumstance that has been a surprise for people who have observed the development of physics in the past half century. The United States was assumed to the superior in engineering and instrumentation, as demonstrated by the development in the 1930s of cyclotrons, synchrotrons, linear accelerators, bubble chambers and so on. But the quality of the engineer-physicists at CERN turned out to be at least as high. They succeeded in constructing accelerators of unusual reliability and flexibility under the leadership of the late Sir John Adams. Some have ascribed this to over-conservative design, but it helped greatly in the exploitation of the machines. Thus it allowed the luminosity of the intersecting storage rings to reach more than ten times the design value, and it facilitated the production of the intense muon and neutrino beams. Finally, it made possible the fast conversion of the 400 GeV accelerator into a proton–antiproton collider, the success of which hung on one of the imaginative devices invented and implemented at CERN by Simon Van der Meer — the so-called stochastic cooling of the antiproton beam, destined to be used in future colliders everywhere in the world.

Furthermore, CERN engineer-physicists led by Kjell Johnson constructed the intersecting storage rings at a time when laboratories in the United States did not dare to take on this difficult task. CERN designed and built the first two colliders for protons, the ISR and the proton–antiproton collider in the SPS tunnel. The effect has been to pioneer a new style of experimentation which has now been taken up by other centres of particle research all over the world. CERN continues the tradition with the large electron–positron collider LEP.

The Martin–Irvine report does not make much of these achievements and also all but ignores the many new ideas for instrumentation spawned at CERN, such as the multiwire proportional chamber and the vacuum ultraviolet imaging device. Both innovations are not only significant advances in detecting particles, but have important applications in medicine and in other sciences.

High-energy physics is an international endeavour, more so than most other scientific activities. There is a constant exchange of physicists and engineers between CERN, the United States and other countries. It does not make much sense to consider progress in this field as a competition between two continents. It is a collective achievement of all participating nations. The CERN effort has contributed essential ingredients. Particle physics would not be what it is without CERN's impetus, without its technical innovations and without its studies and discoveries, even if some of them have not made newspaper headlines.

Last and by no means least, CERN represents the United States of Europe in fundamental physics. It became an active symbol of the spirit of European unity. That is no mean achievement. It serves as the University of Europe for high-energy physics, and brings together the many individual universities in Europe in scientific collaborations of unprecedented magnitude and complexity often involving also universities and institutes of the United States, Eastern Europe and Asia.

In spite of the obvious difficulties which such international collaborations entail, CERN has developed into the foremost high-energy laboratory of the world, as is strikingly confirmed by the recent US panel report on New Facilities for the US High Energy Physics Program, in which it was stated that "the European facilities frequently provide a better level of support and/or a larger number of opportunities than the American equivalents".

How can such an institution be given "Poor Marks for Enterprise"?

VICTOR F. WEISSKOPF

Massachusetts Institute of Technology,
Cambridge, Massachusetts 02139, USA

Victor Weisskopf was director of CERN from 1961 to 1965.

SIR — Robert Walgate's enthusiasm (see *Nature* 6 September, p.4) for the assessment of CERN carried out by two social scientists from Sussex, Irvine and Martin, is misplaced. Most would agree with one conclusion reached by Martin and Irvine, that since the end of the 1960s CERN has been either the leading or next to leading laboratory in the world of particle physics. But their claims to have developed a powerful new tool of assessment in scientific research are exaggerated and their use of it is misleading.

Originally, Martin and Irvine advertised their method as one of "converging partial indicators", based on the questionable assumption that if a variety of uncertain measures appear to agree, the result is reliable. Having applied this method to CERN and found that the indicators do not converge, they nonetheless continue by "interpreting" the non-convergence. Here they rely on an opinion poll of physicists, so the new method boils down to a peer review interpreted by social scientists.

The authors base their main conclusions on a selection of so-called "crucial" experiments. This is hardly the way a serious history of the extraordinary progress in particle physics over the past ten or fifteen years will eventually be written. Such an approach traps the unwary into supposing all other results are negligible, and is a travesty of the basis on which scientific understanding advances. CERN is given credit for the discovery of the weak neutral current, which opened the door for the Glashow–Salam–Weinberg unified theory of the electromagnetic and weak forces and set the stage for much of what has followed. But this discovery did not win a place in the "top eleven" selected by citation analysis.

The method clearly fails seriously in not giving proper weight to several other CERN results of fundamental and lasting importance. For example, experiments at the intersecting storage rings discovered that the strong interactions of the proton are due to point-like constituents; deep inelastic neutrino experiments showed that the weak interactions of the proton also involve point-like "partons" and, when put together with the electron scattering results from the electron linear accelerator (SLAC) at Stanford, demonstrated that the partons are quarks. High-energy neutrino experiments found departures from point-like scattering of a kind attributable to the effects of the quark–quark forces, providing early support for quantum chromodynamics, the now established theory of the strong interaction.

Nevertheless, it is an accepted view that over the decade 1969 to 1978, US laboratories would have appeared more often in a list of top experiments than Europe. Why? Because Martin and Irvine have set themselves the objective of judging CERN, they have no device but to attribute this difference in performance to some inadequacy of managements and physicists at CERN. Unsupported by evidence, they even attribute what they regard as CERN's poorer performance to its being an international laboratory with scientific advisory commitees accountable to national interests. Anyone with the slightest acquaintance with the ways CERN's scientific programme is handled knows there is no such interference; in making this inference Martin and Irvine display such a total ignorance of how CERN actually works that it must invalidate any other conclusions they reach.

With all their great effort of hindsight, Martin and Irvine are yet blind to the single most significant factor in the Europe-United States comparison in the 1970s: the electron-positron collider (SPEAR) at Stanford, together with SLAC, was responsible for the major part of the difference in score on which they hang their case. All will agree that SPEAR was, supremely, the best type of machine for the physics of the 1970s; once this factor is allowed for, the differences are not significant.

No doubt, in retrospect, some decisions of the CERN management and actions of some physicists if differently made could have led to greater success. But this can be said of most scientific endeavours — including those in the United States. What Irvine and Martin seem unable to understand, and what makes their analysis so misleading, is that in research of this nature, until the experiments are done, noone knows which is the best choice. This is why the "methodology" of Martin and Irvine could not have predicted the remarkable success of Stanford in the 1970s.

The authors conclude that after the 1970s, CERN's performance has improved. We are given no "explanation" for this, which the analysis of the preceding years would not have foretold. Their naivety makes any views they express irrelevant to the assessment of any future enterprise such as LEP.

Mental arithmetic

SIR — I was surprised to read in David Singmaster's review[1] of Steven B. Smith's book, *The Great Mental Calculators*, that the mental calculation of the square root of 51 is considered to be so difficult.

I have just calculated the answer to be 7.14142842854216; the last two digits should be 85 I believe. To perform this calculation I have to write down the number (in fact 510,000,000,000 is easier, giving the required answer $\times 10^5$), and also write down and see my growing answer. I have been able to do this for quite some time, but have not developed the capacity, it being of somewhat limited use!

To calculate 1/97 to 96 decimal places, another example given by Dr Singmaster, seems quite easy, and I can multiply three-digit numbers in my head (again, provided they are written down), with a fairly high success rate. From these examples, I could match Alexander Aitken, one of the prodigies cited in the review, but not George Bidder. Indeed I have never thought in terms of logs, as did Bidder — Taylor or Maclaurin series presumably? However I would think that compound interest calculations could be achieved fairly easily by use of suitable binomial coefficients.

As a postdoctoral biochemist I rarely have any call to use such mathematical abilities. But I am astounded that they are thought to be so rare.

Animal rights

SIR — In his article "Animal rights lobby cashes in" (*Nature* 13 September p.95) Marcus Chown points out that it is more than a year since the Government White Paper on animal experiments appeared. Neither in your article nor in recent articles and letters in *The Times* is mention made of certain wording relating to pain which I believe may be responsible for misunderstanding and anxiety. Mr Chown quotes the present rule "if an animal is found to be suffering severe pain which is likely to endure, it shall at once be killed". That is not unfortunately the whole story. Every licence to experiment on living animals carries a list of conditions. The passage quoted is from paragraph 3(b) of these conditions. 3(a) states that if an animal is suffering pain which is either severe or is likely to endure, and *if the main result of the experiment has been attained*, the animal shall forthwith be painlessly killed (italics mine). It is this which gives rise to problems and leads those of a suspicious mind to say that there is always a let-out. An experimenter faced with the loss of valuable experimental material might be tempted to hang on for a few more days until the experiment has been completed, with consequent suffering. This wording must be clarified. An important purpose of future legislation must be to allay public suspicion or disquiet and there must be no suggestion of an easy escape. Paragraph 3(c) of the conditions states that if an Inspector believes that an animal is suffering "considerable" pain he can direct it to be painlessly killed. We thus have pain described as "severe" and "considerable". Since it is impossible to give a clear definition of pain in animals, these terms are of doubtful value. Nevertheless the more moderate animal welfare organizations are right on insisting on some clarification of the "pain condition" and some attempt to balance possible suffering against possible benefits is not unreasonable.

Prizes (at last) for immunology

This week's Nobel prize comes less than 10 years after monoclonal antibodies, already produced commercially as diagnostic reagents. But in that decade, immunology has been transformed.

SOME Nobel prizes are inevitable, the only question being when the nomination will rise to the top of the pile. This year's prize for César Milstein must have been close to the top for at least three years. Nor does it come as any great surprise that Georges Köhler is the second of the three winners of this year's prize for Physiology and Medicine, for he and Milstein jointly discovered the principle of producing monoclonal antibodies. Less predictable is the third winner, Niels Jerne. But to immunologists, Jerne is the great man of influential ideas.

Köhler and Milstein published their paper on "Continuous cultures of fused cells secreting antibody of predefined specificity" in August 1975 (*Nature* **256**, 495). It described how the fusion of a single lymphocyte-secreting antibody with a single bone marrow tumour (myeloma) cell resulted in a hybrid cell with the antibody-producing capacity of the lymphocyte and the immortality of the malignant cell. Their antibody-producing cells came from the spleens of mice immunized with red blood cells from sheep, so that the fused cell lines (hybridomas) each secreted an antibody directed against the sheep cells. Köhler and Milstein emphasized that they could not tell whether similar results would be obtained with other antigens but, obviously believing they could, finished their paper by saying: "It is possible to hybridize antibody-producing cells from different origins. Such cells can be grown *in vitro* in massive cultures to provide specific antibody. Such cultures could be valuable for medical and industrial use."

They were right. Specific antibodies, now known as monoclonal antibodies, are an essential tool of much biomedical research and are of great commercial and medical value. The therapeutic use of monoclonal antibodies is still at an early stage, but they are already invaluable aids to diagnosis and screening. A good example is in blood grouping, where hybridomas established by Milstein are now the basis for the production of monoclonal antibodies on a sufficient scale to replace human sera in ABO blood typing in the United Kingdom.

César Milstein was born in Argentina in 1927, and was on the staff of the Instituto Nacional de Microbiologica in Buenos Aires until 1963, taking time out to obtain a PhD at Cambridge in 1960 as a British Council Fellow. In 1963, he left Argentina to join the staff of the Medical Research Council Laboratory of Molecular Biology in Cambridge, where he has been ever since. He now heads the Protein and Nucleic Acid Chemistry division, which he previously co-directed with Dr Fred Sanger — twice a Nobel Laureate, now retired.

Milstein has always worked on the structure, genetics and evolution of antibody molecules. Perhaps the best known of his "pre-monoclonal" papers is that in *Nature New Biology* **239**, 117; 1972, which demonstrated that the light chain of antibodies is first produced as a larger precursor molecule, whose extra sequence serves as a signal for the process of attachment to, and secretion through, the lymphocyte membrane, during which it is cleaved off. This was probably the first firm evidence to support the signal sequence hypothesis of Blobel and Sabatini.

In 1974, Georges Köhler, then a 27-year-old West German at the Basel Institute of Immunology, obtained an EMBO grant to work at Cambridge with Milstein. His chief interest was the development of antibody-producing cell lines to allow the analysis of the rates of mutation of their antibody genes and so to study the role of somatic mutation in the generation of antibody diversity. It was not by design that monoclonal technology emerged from this research, and the relative contributions of Köhler and Milstein to the discovery is a matter of controversy. The pair have shared some minor prizes, but both the Wolf prize (an Israeli's answer to Nobel) in medicine and the Sloan prize of the General Motors Cancer Research Foundation went to Milstein alone. The Nobel committee has obviously decided that Köhler played a substantial part in the discovery. Köhler returned to the Basel institute in 1976, becoming a permanent member in 1980; he has maintained his interest in the mechanism of antibody diversity. Next March he becomes co-director of the Max Planck Institute of Immunology in Freiburg.

When Köhler returned to Basel it was still under the direction of Niels Jerne, the founding director of the Basel Institute of Immunology, from which he retired in 1980. Jerne was born in Denmark in 1911, started life as a student of physics but soon switched to medicine. From 1943 to 1956 he was at the Danish State Serum Institute and there began his studies on antibodies. He had spells of a few years in Geneva (for the university and World Health Organization), as a visitor at the California Institute of Technology, at the University of Pittsburgh and as director of the Paul Ehrlich Institute in Frankfurt. Technically, his most important paper of that period is probably the description of the plaque-forming assay (*Science* **140**, 405; 1963), a test that allows the quantitation of antibody-producing cells of a particular specificity among a mixed population.

In 1969 when Hoffmann-La Roche founded the Basel Institute of Immunology, Jerne became its first director. During his tenure as director, he became ever more widely acknowledged as the father of several influential, if not always correct, ideas in immunology. In particular he was involved in the theory of antibody selection by antigen — the doctrine that antigens do not instruct the immune system to manufacture new antibodies, but rather select the relevant antibody-producing cell from a pre-existing pool.

Jerne's network theory of immunology, an outcome of his analytical approach to a subject bedevilled by murky observations and operational definitions, was at its most influential about a decade ago. It was based on the fact that antibodies can themselves serve as antigens, Jerne postulated that any antigen would set off a train of events, with each antibody acting also as an antigen and thus linking cells of the immune system in a network since their antigen-binding sites were almost certain to recognize one of the antibodies produced in the course of the response. But in spite of strong experimental evidence in support of the network theory, it remains difficult to determine whether the regulation of most immune responses is substantially controlled in this way.

This year's prizes will be thought well deserved. They will be seen as further justification of the British Medical Research Council's support of basic research at its Laboratory for Molecular Biology in Cambridge. Milstein joins Aaron Klug, Francis Crick, James Watson, Max Perutz and John Kendrew as well as Sanger (twice), whose work at Cambridge brought them a trip to Stockholm. The prizes will also no doubt be seen in certain quarters as a justification of Hoffmann-La Roche's wisdom in founding a basic research institute. But above all this year's Physiology and Medicine prize demonstrates how theory, experiment, curiosity and serendipity can produce not only great scientific insight but what is certain to turn out to be tremendous benefits to mankind.

Peter Newmark

Mineralogy

A continent in a grain of sand

from Bruce W. Sellwood

FOR well over sixty years the abundance, identities and assemblages of minerals in sandstones have been used in the determination of sediment provenance in order to reconstruct the geography, climate and geology of sediment source terrains of the past. Recently, it has been realized that sandstone composition is to a large degree also governed by plate tectonics. Provenance studies of modern sedimentary systems have previously been carried out on the scale of individual basins, but not for a whole continent. Now on page 645 of this issue, Potter describes the mineralogy of sands from the beaches of South America, and interprets it in terms of the palaeotectonics of the continent.

In ancient systems, the petrography of sandstones has been used in the interpretation of the geotectonic regimes of depositional basins, such as a passive continental margin or a fore-arc basin, and of source areas,despite the fact that sand is recycled from older sandstones. Geotectonic interpretations rely heavily on observations and assumptions of the probable composition of typical terrestrial terrains. It is argued that quartz-rich sediments are associated typically with passive continental margins and that quartz-poor sediments are mostly of volcanic origin in magmatic arcs. Sediments of intermediate quartz content are generally believed to be associated with active continental margins and orogenic belts while arkosic (feldspar-rich) sands are often derived from uplifted basement rocks adjacent to rifts and wrench faults. Other factors, such as climate and the length and vigour of streams, are considered to tune the ultimate composition of deposited sands.

The validity of these palaeotectonic models can be tested only in terms of large-scale modern investigations and this is the significance of Potter's study. He chose South America because it has a well-developed active margin on its west coast, a passive margin on its east coast, with transcurrent motions affecting only the Caribbean border zones. Although lacking significant continental glaciation it exhibits major climatic belts lying transverse to the Andes. Potter's is the first report on the petrography of sands from within the same environmental regime (beaches) around an entire continent and thus is highly significant, even though the results come from only about 200 samples.

Much of the sediment arriving on continental beaches is derived from rivers and Potter argues that its mineralogy is likely to have been extensively modified by abrasion. Furthermore, if the mineralogy of beach sands closely relates to the tectonic setting of adjacent land areas, then that of the local river sediments is likely to be even more closely related. The results of the study confirm the predictions of earlier workers (for example, Dickinson, W.F.R. & Suczek, C.A. *Bull. Am. Ass. petrol. Geol.* **63**, 2164; 1979). On its leading margin (the Pacific coast), quartz comprises only 19 per cent of the mineral and so is subordinate to rock fragments and feldspar, while on the trailing margin (Atlantic coast) it comprises, on average, 96 per cent of the mineral, even where mountains of Precambrian crystalline rocks border the coastline.

Some anomalous patterns exist, however, indicating that results from ancient sequences must be interpreted with some caution. Although sited on a trailing margin, the Argentine coast from Rio de la Plata to Tierra del Fuego has an Andean (leading-margin) composition, being dominated by volcanic rock fragments. This is partly because Pategonia is too narrow to allow abrasive processes to be completed and partly because the coastal bedrock is itself immature young sediments recently derived from the rising Andes.

This work thus confirms the view that the detrital mineralogy of ancient sandstones may be used successfully in the reconstruction of palaeoplate settings.

Although the predicted patterns of mineralogical provinces are generally confirmed in the study, further questions need to be answered. For example, what subtle effects does climate have on the rate of degradation of certain types of rock and mineral species during transport? In what way does the interaction between relief, transport distance and rainfall favour either the elimination or preservation of unstable grains? And to what extent do the boundaries between mineralogical provinces coincide with major physiographical features such as large river mouths?

Potter's study is merely a first step, doing for grains on a continental scale what clay mineralogists have already done for mudrocks on a global scale (Griffin, G.M., Windom, H. & Goldberg, E.D. *Deep Sea Res.* **15**, 433; 1968). As Potter observes, if his models stand up to further scrutiny, the next stage will be deduction of sand composition over all types of environment of an entire continent (or palaeocontinent). Because the depositional maturity of sediments is a key factor in their behaviour during burial, predictive models based on studies such as Potter's bear directly on the assessment of regional porosity and permeability trends in hydrocarbon reservoir rocks. ☐

Astronomy

Nemesis for Nemesis?

from Mark E. Bailey

LAST spring, great interest and excitement were generated by the idea that a hypothetical companion star of the Sun, called Nemesis by some, could trigger the periodic sequence of extinction events found in the fossil record[1-5]. Now, only six months later, another collection of papers on the same subject (see pages 635-642) gives what amounts to a considered reflection on the model.

Interest in Nemesis began about a year ago[4], following the claim by Raup and Sepkoski to have identified a regular 26-Myr periodicity in the fossil record, with a confidence level of better than 99 per cent. The evidence that the sequence of events was periodic was further strengthened by an independent analysis of the cratering record[3], which produced a period and phase for the cyclicity agreeing with that of the fossil record. These arguments for strict periodicity in the geological record can be challenged at a number of points[5], although the independent evidence for rough periodicity as, for example, in the sense that the solar sunspot cycle is 'periodic', is probably less easily denied[6-8].

But if the cratering and extinction record is strictly periodic, which will be settled only by further detailed research on the geological front, it is clearly important to devise explanations, and this is the spirit in which the Nemesis proposal was made. Thus, it was argued, the orbital period of the hypothetical companion should give the strict periodicity required, while its gravitational influence on the comets in a hypothetical dense inner core of the Oort cloud might produce periodic comet showers in the manner outlined by Hills[9]. The further possibility that Nemesis (or Planet X) might show up in the Infrared Astronomical Satellite data also gave piquancy and a certain urgency to the debate.

In the papers published in this issue of *Nature*, the Nemesis proposal is extended and shown, in fact, to be quite incapable of producing the strictly periodic sequence of extinction events for which it was originally designed. The stability of the orbit has been investigated by Torbett and Smoluchowski[10], whereas Hills[11] and Hut[12] show in particular that when stellar perturbations and the overall tidal field of the Galaxy are included, the orbital period should drift towards larger values by about 15 per cent or more over the 250-Myr time scale considered by Raup and Sepkoski. The probably dominant effects of giant molecular cloud perturbations would further reinforce this conclusion, and cast serious doubt on the likely survival of such a solar companion for the age of the Solar System[10,13]. Of course, it is conceivable that the star might have been recently captured or scattered to its present orbit from a more tightly bound state with much shorter period, but these suggestions beg many questions. In any case, as shown by Hut[12], it appears that the Nemesis proposal — if correct — does not predict a constant interval between extinctions. A re-analysis of the fossil record may agree with this new prediction[2], but this has not yet been carried out.

The alternative, that extinctions are quasi-periodic, was explored last April in two papers[14,15] and is now reviewed in detail by Clube and Napier[13], who argue strongly against the Nemesis proposal and come down in favour of a galactic connection, as they have advocated for some time[6,7,16].

In view of these developments, one might possibly be excused for regarding this episode of hypothesis followed by near-retraction as yet another example of the explosion in the volume of the literature, and of the over-rapid publication of speculative ideas. Previous commentaries[4,5] already hinted at this, and it is therefore perhaps not wholly out of place to consider the point further. Although some cynicism is doubtless justified and can easily be understood, to hold such a view exclusively is, in my opinion, to miss the point. It is often the case in astronomy, and no doubt other subjects, that the various pieces of a puzzle can be assembled in a number of ways and still explain the same data. Indeed, it is an important part of a theorist's job to do just that, and provided the proposed hypotheses take all the facts into account and are not obviously so contrived as to be subject to Occam's razor, the more possibilities the better. This in spite of the reality that no more than one can be true. Science often progress by mistakes and it is therefore too easy simply to dismiss speculative suggestions as a kind of non-science.

In the present case, the argument for Nemesis causing mass extinctions is indeed highly speculative since it assumes the existence of the star, the presence of a dense inner core to the Oort cloud, the regularity of the extinction cycles and the possibility that impacts trigger extinctions. Yet whatever the final decision about the existence of the star, the benefits of the suggestion have already outweighed any temporary nuisance or adverse reaction it may originally have caused. For example, the shape of the Oort cloud and the stability of comet-like orbits under the perturbing action of passing stars, gas clouds and the Galaxy, are crucial to an understanding of cometary origins. Moreover, the papers now published have a clear connection with studies of binary stars and of their long-term orbital stability, while the connection between these kinds of problem and studies of open star clusters has already been noted[17].

On the geological front, I am less qualified to judge, but if the Nemesis saga has served only to increase general awareness that cometary impacts may frequently occur, then it will have been beneficial. Ten years ago the idea was hardly considered, and even last year, at the Brighton meeting of the British Association for the Advancement of Science, it was dismissed. Yet the most conservative Oort cloud model predicts some cometary impacts, and presumably they do have some influence worth exploring.

Finally, if the extinction sequences should somehow be shown to be strictly periodic, it may be worth noting that there is already a new variant on the Nemesis theme[18] — in which comet showers are still predicted to be periodic. To mix two metaphors, though there may be smoke without fire, perhaps even the darkest clouds have silver linings. ☐

Behavioural ecology

Optimal foraging theory tested

from Jared M. Diamond

A KEY postulate of behavioural ecology is that animals practise 'optimal foraging'. That is, animals forage for food in a way that maximizes some function such as the rate of energy gain[1,2]. A paper by Carpenter *et al.* describes an ingenious experiment designed to test the theory of optimal foraging[3].

Consider the territory size of an animal attempting to maximize its daily net energy gain. Optimal foraging theory argues that a territory yields benefits (especially food resources), which increase in proportion to territory size up to a ceiling set by an individual's food-processing abilities or time constraints. An increase in territory size also incurs increased costs of travel time and territorial defence against intruders. Supposedly, individual energy-maximizing animals can both assess and achieve an optimal territory size at which the difference between the benefits and costs represents a maximal rate of energy intake.

While much animal behaviour is roughly consistent with this view, it has proved very difficult to devise quantitative tests of the optimality principle in the field. A suitable test would require measuring an animal's rate of net energy intake (approximated by its rate of weight gain) as a function of the parameter putatively optimized (for example, territory size). One could then examine whether the rate of weight gain does peak at intermediate territory sizes, and whether individuals adjust territory size towards this optimal value.

How could one perform such a test? Periodically capturing a wild animal to weigh it has the obvious drawbacks that one can rarely count on capturing an individual at fixed intervals, and the disturbance associated with capture is likely to influence the results. The ideal solution would be to induce an animal to weigh itself repeatedly. It is this task of persuasion that has recently been achieved by F. Lynn Carpenter, David C. Paton and Mark A. Hixon, working with rufous hummingbirds (*Selasphorus rufus*) of western North America[3].

Like most other migratory hummingbird species, the rufous faces severe energetics problems. In July and August of each year the birds migrate at least 3,000 km south, along mountain ranges, from their breeding grounds (Oregon to Alaska) to their wintering grounds in southern Mexico[4]. To fuel their flight, these 3-g birds stop en route, defend feeding territories and gain at least 1.5 g of fat in 1–2 weeks before resuming migration. At this season, migration in the mountains is risky: rain, hail and wind often prevent feeding, destroy the flowers that serve as nectar sources and even endanger the birds themselves. Thus, individuals should be selected to make few stops, and to fatten up quickly and maximize daily net energy gain while on stopover, so as to complete the migration as quickly as possible.

In order to obtain exclusive access to the nectar of flowers[5,6], hummingbirds engage in two types of fierce competition for territories. First, territory-owning hummingbirds spend much time and energy driving off intruding hummingbirds and sometimes bees, hawkmoths and butterflies which drink the same nectar ('interference competition')[7]. Second, territory holders start off each day by depleting the nectar in the flowers at the periphery of their territories[8]. Since intruders mainly try to rob peripheral flowers and return to sites where they were previously successful, early-morning peripheral foraging by the territory owner spoils the territory for intruders ('exploitation competition').

In 1979, Carpenter and her colleagues tested a model of optimal territory size[9] by covering half the flowers in a hummingbird's territory with plastic bags[10]. They found that within one day the bird increases its territory size to maintain the original number of defended flowers, and then abandons the extra area when the bagged flowers are unbagged on the next day. This experiment shows that the benefit gained from territory size is control of food, and that hummingbirds are capable of measuring their nectar intake or nectar resources. The experiment does not assess, however, whether the preferred flower supply is optimal, as defined by maximization of weight gain.

In 1980 the following direct test was devised. A hummingbird spends about 75 per cent of each hour quietly perched on one or two preferred twigs while clearing its crop of nectar between foraging bouts. Carpenter and colleagues replaced these twigs with a Pesola spring balance, modified to carry a perch on top and to function by being depressed from above rather than stretched from below. The bird accepted this perch, thereby enabling Carpenter *et al.* to sit with a telescope outside the territory boundaries and periodically read off the bird's weight to ±50 mg. In 1982 the spring balance was exchanged for a Mettler electronic balance whose pan had been replaced by a perch. With the resulting weighing accuracy of ± 10 mg, the biologists could detect a hummingbird's weight gain in a single foraging bout or its weight loss on defaecation.

As an example of the results, consider bird WP, who was first observed on 23 July as a lean individual weighing 3.1 g. On 27 and 28 July WP had a relatively small territory containing 1,970 flowers and gained weight at the low rate of 0.10–0.15 g per day. On 29 July WP nearly doubled its territory size to 3,320 flowers and increased its weight gain to 0.25 g per day. The following day it relinquished half of the extra flowers to achieve its maximal rate of weight gain of 0.35 g per day, and it maintained this territory for another day. It thus reached a weight of 4.6 g by the morning of 1 August and took off on migration.

The results with WP and other rufous hummingbirds reveal that the birds adjust their territory size by trial and error until they have maximized the rate of weight gain[3]. Territories that are either too large or too small yield reduced rates. Hence, this system supports two basic postulates of optimal foraging theory: the birds can detect changes in energy intake, or a correlate of it, and they apparently adjust territory size to maximize energy intake. More generally, however, this study offers a method of repeatedly weighing a wild animal without disturbance. With further ingenuity the field balance technique could be applied to other animal species that periodically return to one or a few preferred sites. Such regular weighings of wild animals could elucidate behavioural, physiological and ecological problems, such as ones related to foraging, water loss and reproduction. The new method may provide a breakthrough in field biology. ☐

Developmental biology

Autocrine control of growth?

from C.D. Stiles

IN the 'autocrine growth' scenario for malignant transformation, popularized by Todaro, DeLarco and others[1], cancer is initiated when a cell begins to produce a growth factor for which it has receptors and to which it is responsive. When this factor binds to receptors on the cell from which it has been secreted, a self-perpetuating automitogenic response is triggered. Within this context, autocrine growth is seen as a perversion of normal information flow, it being tacitly understood that growth factors, like conventional hormones, function normally in the paracrine or endocrine modes — that is, they communicate between heterologous tissues and are synthesized at some distance from the target cell. A letter in this issue of *Nature* challenges this precept; in it, Seifert *et al.* describe the developmentally regulated synthesis of a growth factor that may normally function in the autocrine mode[2].

Ironically, platelet-derived growth factor (PDGF) serves as the point of departure for the studies of Seifert *et al.* It is recent insights into the molecular biology of this molecule (reviewed in ref. 3) that provide the strongest support for the autocrine theory of malignancy. High-affinity receptors for PDGF are confined to a well-defined subset of animal tissues — only fibroblasts, glia and arterial smooth muscle cells display them, and only these cells show a growth requirement for PDGF in culture. Last year, the c-*sis* oncogene was shown to direct synthesis of a functional PDGF subunit. As expression of this gene is (almost) exclusively confined to cells derived from connective tissue neoplasms, it can be concluded that synthesis of the sis protein (PDGF) *in vivo* provides a selective advantage only to cells that express PDGF receptors.

Seifert *et al.* report that cultured aortic smooth muscle cells isolated from 13 – 18-day-old rat pups secrete a growth factor that competes with authentic human PDGF for binding to fibroblasts. This cellular PDGF-like material (which they term PDGF-c) is recognized by anti-PDGF immunoglobin and is mitogenic for 3T3 cells. Comparable smooth muscle cells isolated from adult rats secrete little, if any, PDGF-c. The inability of adult cells to generate PDGF-c does not merely reflect the passage of time or cell divisions, because the pup smooth muscle cells continue to secrete PDGF-c during 20 passages in culture and over a 6-month interval. The authors conclude that synthesis of PDGF-c is developmentally regulated. They speculate that the substantial increase in both the number of smooth muscle cells and the thickness of the connective tissue matrix of the rat aorta, that occurs within the first three months, reflects an automitogenic response to PDGF-c.

Synthesis and secretion of PDGF-c by pup smooth muscle draws attention to a broader body of literature on the production of growth factors either by normal diploid cell cultures derived from embryos or by embryonal carcinoma cell lines. Substances identical to, or closely related to, nerve growth factor, transforming growth factors and colony-stimulating factor are synthesized by these cells[4-6]. Two recent studies echo the developmental control observed by Seifert *et al.* First, Nissley, Rechler and their co-workers have shown that diploid fibroblast cultures derived from neonatal rats secrete the neutral form of insulin-like growth factor (IGF-II) which seems to modulate growth *in utero*. Comparable cultures established from adult rats secrete the basic form (IGF-I) which is the dominant factor in skeletal development of juveniles and adults[7]. Second, Clemmons has noted that while fetal fibroblast cultures secrete a functional homologue of PDGF, comparable cultures derived from human donors aged three or more do not[8]. Though Clemmons did not have the PDGF radioreceptor assay at his disposal, it seems plausible that the mitogen he observed is the PDGF-c described by Seifert *et al.* The plethora of growth factors secreted by embryonic cells, the developmental control of their production and the early appearance of growth factor receptors in embryogenesis[9] support a popular prejudice that the serum growth factors, scrutinized so thoroughly within the context of tumour biology, may play pivotal roles in developmental growth and morphogenesis.

The new twist provided by Seifert *et al.* is the suggestion that 'embryo-derived growth factors' function normally in the autocrine mode. On first consideration the concept is aesthetically distasteful. Why should a developing tissue secrete a growth factor to stimulate its own proliferation? Surely the process could be controlled more stringently from within the cell at some point subsequent to the events governed by growth factors and their receptors. A teleological rationale may be contained within the biological need to amplify weak chemical signals — the *raison d'etre* of membrane-bound receptors for hormones and growth factors. It is worth noting that normal embryo fibroblast cultures typically require less serum for growth than do established lines of the 3T3 genre, an observation consistent with the view that embryonic cultures respond to the growth factors they produce. Furthermore, another growth factor, interleukin-2, seems normally to function in the autocrine mode[10].

The interface between growth factors and development remains even less than tenuous. Nonetheless, if recent observations can be extended, the implications are wide indeed. Growth factor receptors and other components of the 'mitogenic cascade' may be vestiges of an automitogenic apparatus used in development. By switching off the gene encoding an automitogen and activating the same gene at some distal site, the developmental machinery may be neatly converted to the paracrine mode. In this state, it could promote cell proliferation 'on demand' during adult life in, for example, wound healing, erythropoiesis and immunogenesis. Switching errors in adult life would manifest themselves as proliferative disorders — keloids, psoriasis, atherosclerosis and, of course, neoplasia. ☐

Biophysics

Many guises in Bristol

from Maxine Clarke

There probably never was an adequate definition of biophysics. Perhaps there never will be. That, at least, seemed to be one inevitable conclusion of the 8th International Congress of Biophysics held in Bristol, 29 July — 4 August, at which it became clearer than ever just how many biological questions have recently been annexed by biophysicists.

For example, T. Wiesel (Rockefeller University) presented one classic physiological study in the guise of biophysics in reporting how electron microscopy has been used to demonstrate axonal spread of peroxidase-stained neurones throughout several hierarchical levels of organisation in the visual cortex. Physiological experiments on monkey photoreceptors (D. Baylor, Stanford University) show that both rods and cones have identical properties to those deduced by psychophysical studies in man. Many other biological questions, from how ion channels are gated to how microtubules cause cilia to beat, were similarly addressed in biophysical fashion.

To anyone with a primary interest in the structure of cells and organelles, it was very obvious that improvements in electron microscopy and synchrotron radiation measurements had contributed greatly to progress since the 7th congress, three years ago. An optical diffraction pattern taken from an electron microscope image contains information about the phases as well as the amplitudes of the reflections. This inherent advantage of electron microscopy over X-ray diffraction techniques has been limited by problems in the resolving power of the method, but the use of low electron dose to eliminate beam damage to the specimen and the development of cryomethods which do not require staining of the specimen are solving some of the problems. Such improvements enabled E. Kellenberger (University of Basel) to show that the bacterial cell envelope has a periplasmic gel of regular thickness between the inner and outer membranes, with the nucleoids (bacterial DNA) much freer than originally thought. The dependence of nucleoid structure on environmental conditions is now being measured by a freeze-substitution technique. J.L. Carrascosa (Universidad Autónoma de Madrid) produced a 2.2 nm-resolution three-dimensional image of the head-to-tail connection (neck region) of the 029 bacteriophage by tilting a two-dimensional hexagonal array of necks and performing a Fourier analysis of differently angled views of the section. The inner region of the neck was identified as the part interacting with the DNA; it has 6-fold symmetry and the proteins constituting this and the 12-fold outer neck region have been assigned.

Improvements in synchrotron radiation techniques have enabled some of the predictions of the crossbridge theory of muscle contraction to be confirmed for the first time. A two-dimensional detector allows a difference pattern between relaxed and contracting muscle to be produced. H. Huxley (MRC laboratory of Molecular Biology, Cambridge) reported an increase of the actin (thin filament) reflections on contraction; this result is the necessary outcome of the attachment of crossbridges from the thick to the thin filaments but had not been visualized previously. His group has also found that the part of the diffraction pattern that arises from the calcium-binding proteins changes before the part that is related to the crossbridges. This confirms the hypothesis that calcium binding has a structural consequence which must express itself in the muscle filaments before the crossbridges can produce force. In a different approach to elucidating the mechanism of contraction, Y. Goldman (University of Pennsylvania) described an ambitious attempt to link the biochemical rate constants of the muscle's ATPase, derived from solution studies of muscle proteins, with the force-producing properties of the fibres. Caged ATP, an inert molecule which can be photolysed to ATP with UV light after its infusion into a muscle fibre, is used in this approach. Several of the kinetically intermediate reactions in the ATPase in muscle fibres are similar to those in solution, so that the particular step in the biochemical pathway affected by force can now be sought.

Innumerable other topics, ranging from atomic interactions in proteins to the role of biophysics in university teaching courses, were discussed at the meeting. The main virtue of the conference lay in the manner in which a review of a huge number of topics, via sessions centred around either a biological problem or a physical technique, was arranged. This was particularly valuable for highlighting old problems which might now be solved using new methods. Individual sessions did not necessarily provide a balanced view of the field under discussion, but that is always likely to remain the case at the International Congress. The annual meeting of the US Biophysical Society attracts universal attendance and is established as the forum for comprehensive discussions in a large number of subjects. This is more difficult to achieve in a nomadic meeting in which there is a necessarily random sampling of a much wider population. However, for those biophysicists with time and desire to expand their education, looking for a new problem or interested in new methods, the International congresses remain a valuable venue. ☐

Geology

Submersible study of the East Pacific Rise

from members of the Geocyarise expedition

ON 5 March 1984 the French research vessel *Nadir* docked at Manzanillo, Mexico, at the end of a highly successful leg of diving operations on the East Pacific Rise using the submersible *Cyana*. Several key sites between 11° and 13°N were explored, with the specific aim of studying hydrothermal processes.

Previous investigations by French vessels had established, near 12°50′N, the existence of a narrow zone (less than 200 m wide and 20 km long) of intense hydrothermal activity believed to be due to the presence of a shallow magma reservoir beneath the axis. The East Pacific Rise in this vicinity is conspicuously asymmetric, with off-axis seamounts on one side and linear normal faults on the other. Geological reconnaissances were carried out on four seamounts located 4 km west of the rise axis near 11°30′N(A), 18 km west of the axis at 12°38′N(B), 6 km east of the axis at 12°43′N(C) and 6 km east of the axis at 12°50′N(D).

Seamounts A and C, which are structurally similar and rise less than 400 m above the surrounding sea floor at 2,700 m, were explored extensively. Linear north–south aprons some 500 m long and less than 100 m in relief extend south from the eastern and western margins of both seamounts. Extensive hydrothermal deposits found on seamount C during a *Cyana* dive in 1982. On this leg, highly-altered fragile hydrothermal edifices several metres high were found around an apron of seamount A. Its western flank consisted of a vertical fault scarp with extensive piles of talus at its foot composed of sulphide boulders and fragments of massive flows. Extensive areas of Fe oxides, hydroxides and thick (> 2 cm) Fe–Mn crusts were encountered during dives from the southern foot of the seamount to its top.

Three dives confirmed the existence of a massive sulphide field capped with ochreous oxidation products on the western limb of an apron of seamount C. Hydrothermal material extends at least 800 m down the south flank of the seamount from its top and some 500 m in an east–west direction along the 2,600 m isobath. Assuming the deposit to be, on average, 3 m thick and to have a density of 3.0 g cm^{-3}, its mass is conservatively estimated to be more than 2×10^6 tonnes. Metal contents in the deposit are in the range 20–40 per cent Fe, 1–3 per cent Cu and less than 1 per cent Co. This deposit differs from those on the adjacent Rise axis in its massive appearance, its relative depletion in zinc sulphide and its abundance of hydrated silica. The smaller size (<50 m diameter) and richer metal (Cu and Zn) content of the Rise axis deposits suggest a faster deposition at a higher temperature than occurred for the seamount deposit. The age of the deposit on seamount C is unknown, although the lack of sediment cover indicates a relatively recent origin. The crust on which the seamount lies is approximately 100,000 years old. The occurrence of fresh pillow flows partially covering some of the ochreous hydrothermal products indicates off-axis volcanic activity. Interestingly, near the base of the seamounts at 2,700 m depth the pillow flows are almost entirely covered by pelagic sediment.

A semicircular volcanic structure located between seamount C and the rise axis showed evidence of recent off-axis hydrothermal activity. A diffuse white fluid was exiting from hydrothermal edifices on top of a volcanic peak (<50 m in height) made up of fresh sheet flows, and a large amount of ochreous sediment with slumped boulders of massive sulphide was observed at its base.

Two dives took place on the eastern margin of the axial graben near 12°50′N in order to study the alteration and mode of emplacement of sulphide precipitates at recently active hydrothermal sites. A field of green-coloured altered pillows and flows mixed with sulphide boulders, which formed piles of talus at the foot of a 30 m high fault scarp, was observed. Along the wall was an extensive stockwork of sulphide filled veins (<50 m wide) within altered country rock containing chlorite–smectite–sulphide assemblages typical of low-grade metamorphism.

The offset spreading centre discovered by Macdonald and Fox (*Nature* **301**, 55; 1983) at 12°53′N was the target for another dive. The eastern segment seemed relatively old, with flows and pillows partially covered by sediment. The western ridge is marked by a small graben (some 10 m deep and 30 m wide) containing fresh lobated flows but discontinuous along the axis. The sporadic occurrence of *Galathea* and brachyuran crabs indicated hydrothermal activity nearby. Proceeding northwards along the western axis the basaltic flows become fresher in appearance (very shiny glassy surfaces) and ochreous sediments more common, suggesting increasing hydrothermal activity. By contrast, the eastern ridge at the same latitude is apparently inactive and being tectonically disrupted.

The first electrical resistivity measurements of the seabed to be made from a submersible were carried out by T.J.G. Francis of the Institute of Oceanographic Sciences, UK. At each site an electrical cable 50 m long was laid along the bottom. Current was passed between electrodes 30 m apart by means of a 12 V battery within the submersible and voltages were detected by Ag–AgCl potential electrodes. The resistivity of the pillow lava terrain was about 40 times that of seawater, in good agreement with downhole logging measurements in DSDP drill holes. The resistivity of the sulphide deposit was between one and two orders of magnitude less than that of the pillow basalts. At one site the seabed was approximately twice as conductive as the seawater and preliminary measurements suggest the sulphides could be of the order of 15 m thick. Self potentials were observed associated with the sulphide deposit.

Electrical potentials were also measured in the water column in order to determine whether hydrothermal fluids exiting from the seabed create masses of water with a different (redox) potential from the adjacent water mass. This experiment, devised by F. Avedik of CNEXO-COB, consisted of measuring the potential difference between one non-polarizing electrode held at 150 m depth and another lowered to the ocean floor at a depth of 2,600–2,900 m. Negative anomalies with amplitudes of 6–8 mV were observed next to the sea floor, some of which extended up to 500–600 m above the bottom. This type of measurement could prove to be a useful way of detecting the presence of hydrothermal activity. ☐

100 years ago

THE PRIME MERIDIAN CONFERENCE

THE Prime Meridian Conference at Washington on Monday adopted the Greenwich line as the universal prime meridian. Only one vote — that of St. Domingo — was given against its adoption; but the representatives of France and Brazil declined to vote.

To the American resolution for adopting the Greenwich line, Mr. Fleming (Canada) moved an amendment to the effect that the Conference should adopt the 180th degree of longitude east from Greenwich as the prime meridian; but the other British delegates opposing the proposition, it was lost. M. Lefaivre (France) said the Greenwich was not a scientific meridian, and that it implied no progress in any science, but was merely a commercial standard. Since, therefore, nothing would be gained to science by adopting Greenwich, France could not make a sacrifice of her own meridian, and incur the vast expense consequent upon the adoption of a new one, because she would thereby gain no advantage whatever. Sir William Thomson said that it was purely a matter of convenience, and that Greenwich answered the world's convenience better than any other standard meridian.

Space programmes

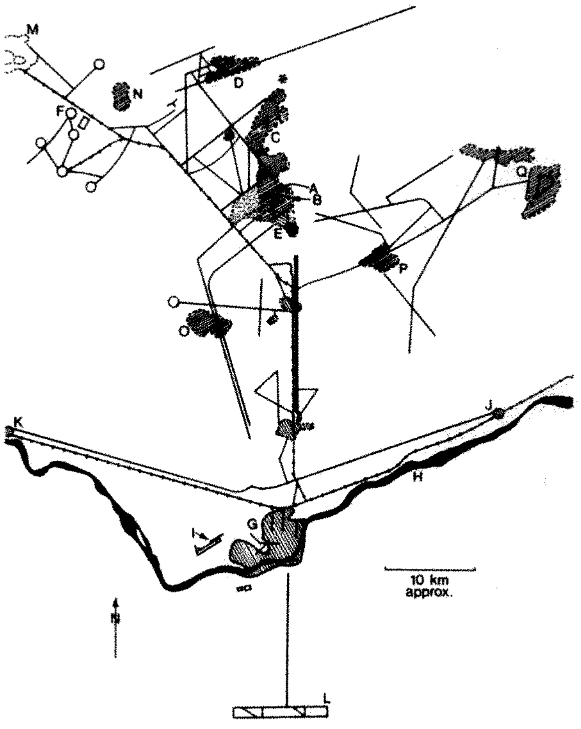
Details of Soviet cosmodrome from space shuttle photographs

from Grant H. Thomson

EVIDENCE that the Soviet Baikonur Cosmodrome is situated at 63.3°E, 46.0°N has already been provided by the remote-sensing Landsat multispectral and return-beam vidicon systems. But that evidence has recently been supplemented by two colour photographs (NASA 84-HC20 and 84-HC-22) obtained using a hand-held camera, with 100 mm and 250 mm lenses, during the flight of STS-9, *Columbia* (1983-116A), in December 1983. Although the ground-resolution of the photography is not particularly good, it is sufficient to add some useful up-to-date detail to maps published by observers of the Soviet space programme.

So far as is known, the Soviet authorities have not yet published, for general reference, a map of the Tyuratam area showing the cosmodrome. They have, however, announced the geographical coordinates of the manned-spaceflight launch pads at 65.5°E, 47.3°N, and press briefings for the Apollo–Soyuz Test Project have the launch site as 66.0°E, 47.8°N, presumably based on Soviet information. These coordinates place the Baikonur Cosmodrome well to the north-east of the extensive launch facilities just north of the old town of Tyuratam. Recently, former CIA official and photo-interpretation expert, Dino Brugioni, has explained how U-2 photography enabled the site to be located, following intelligence reports in the 1950s of a missile site somewhere south of the Aral Sea (*Air Force Mag.*, 108; March 1984). In the absence of any Soviet acknowledgement at the time of such a facility, a war-time German map, showing Tyuratam as a nearby railway station, provided the name by which the cosmodrome has become widely known in the West.

The STS-9 photographs indicate extensive disturbance of the steppe over an area in excess of 150 km², in region C of the accompanying map, which is based on photography. Most noticeable in this area are the three very large new buildings (A) which, because of their size, are probably vehicle assembly buildings. The approximate dimensions of one of these buildings is 220 m × 190 m × 23 m; another is 220 m × 80 m × 35 m; the third has dimensions 155 m × 110 m × 23 m. At B, approximately 2 km to the north-east of these three buildings, the shadow of what is possibly the new heavy-lift vehicle, once referred to as Type G, can be seen. From the solar elevation and the length of the shadow, the vehicle would appear to be more than 90 m tall, in good agreement with Vick's speculation (*Spaceflight* **25**, 159; 1984).



A, Probable new vehicle assembly building. B, Possible new heavy-lift vehicle. C, New area showing signs of construction, including a launch pad. D, New runway and supporting facilities. E, Possible Soyuz assembly facilities. F, Military launch area. G, Tyuratam old town and new city of Leninsk. H, Syr Dar'ya river. I, Airport. J, Diirmentobe. K, Bay-Khoza. L, Possible air defence airfield. M, Possible old quarry site. N, Possible technical site. O, Possible technical site. P, Probable technical site. Q, Possible technical site and/or launch-pad facilities.

Map of the Soviet Baikonur Cosmodrome at Tyuratam constructed from photographs taken from the space shuttle *Columbia*.

There is a V-shaped feature in the northern part of area C, strongly suggestive of a large new launch pad and associated flame-pit. Its size and probable recent construction suggest that it could be the launch facility for the new heavy-lift vehicle. Area E is shown on Vick's maps as facilities for the long-serving A-vehicle (*The Illustrated Encyclopedia of Space Technology*, 39, Salamander, 1981; and *Soviet Space Programs: 1976-80*, Pt 1, 48, US Govt Printing Office, Washington DC, 1982).

A new runway is under construction at D, in the more northerly part of the cosmodrome. At the time the photographs were taken, this was some 5 km long and may not yet have been completed. Extending from and in line with the runway, in the direction of the typical launch azimuth, is a track across the steppe, approximately 20 km long, that may indicate future development. Buildings and signs of construction activity in an area on the north side of the runway are thought to be the Soviet 'spaceplane'.

The ground in the area N shows some evidence of disturbance compared with the surrounding steppe, possibly indicating some work in progress at that site. The terrain in the area M appears very uneven, unlike the rolling or fairly flat surrounding region. This could have been a quarry site and a rectangular structure, approximately 250 m long, can be seen at the north-west limit of the area.

Area F has been identified by Vick as a military launch complex (*Soviet Space Programs: 1976-80*), and possible sites of launch pads or silos are marked with circles. An unidentified rectangular feature, 1,400 m × 750 m, can be seen close to the south-west side of the railway. Sites O and Q show extensive activity, with Q thought to include launch-pad facilities at the end of the railway line. The nature of the large area immediately to the south-east is uncertain, although extensive linear features can be seen. At least two sizeable structures can be seen at P which, although not fully recognizable, is likely to be a technical site.

Just less than 20 km south of Tyuratam are what appear to be parallel runways. If this interpretation is correct, they are likely to be part of an air defence system which almost certainly will have been provided for the cosmodrome. The location would provide airspace clear of the launch complex.

Although the photographs do not provide great detail, they clearly show the extensive activity now in progress at the Baikonur Cosmodrome and provide a good guide for the West to the Soviet authorities' intention of continuing with their investment in space programmes. ☐

Astrophysics

Neutrinos and the Sun

from Virginia Trimble

NOTHING can replace real data from a working scientific experiment. This was the most important lesson to be learned by the participants in the Homestake Neutrino Conference*. Among the questions addressed, for which there either are, or should be such data, were the following. (1) What is the flux of neutrinos hitting the Earth? (2) How does it depend on time and neutrino energy? And (3) what is the Sun doing in addition to (or instead of) making neutrinos? In short, the answers are, for (1), still puzzlingly low; for (2), possibly variable with an 11 yr period; and for (3), perhaps stirring its interior, probably driving its magnetic field with a dynamo at the base of the convection zone, and, just maybe, showing a solar activity cycle as far back as 700,000,000 yr.

First the incident flux. There cannot be a physicist, astronomer, or chemist who has not heard of Raymond Davis Jr and his 100,000 gallons of cleaning fluid (C_2Cl_4) in the depths of the Homestake Mine. The experiment was designed to permit recovery of a few atoms of ^{37}Ar, resulting from the decay of ^{37}Cl driven by neutrinos from the Sun. The counting rate from the recovered atoms has persisted for more than a decade in being about one-third of what theorists predict from solar neutrinos alone (observed production rate 0.39 ± 0.05 atoms per day = 2.1 ± 0.26 SNU, after subtracting the current best estimates for assorted backgrounds). There is now no serious doubt about the atoms' identity: they not only have the chemistry and decay energy of ^{37}Ar but also have its half life (J. Rowley, Brookhaven National Laboratory). But the fraction of ^{37}Ar production that should be attributed to backgrounds from cosmic-ray secondaries has become less certain. Two backgrounds are important, muons and neutrinos. E. Fireman (Center for Astrophysics) is currently checking the muon background adjacent to Davis's tank using several thousand gallons of potassium hydroxide. The rationale behind his experiment is that cosmic-ray particles can be expected to make ^{37}Ar from ^{39}K at about the same rate as from ^{37}Cl, whereas neutrinos will make far less. His 1σ limits on particle production of ^{37}Ar are currently 0.20 ± 0.20 atoms per day, consistent either with the standard best estimate of 0.08 atoms per day or with the entire observed rate of 0.47. Longer runs should tighten the error bars considerably. The flux of cosmic ray-produced neutrinos can easily be checked only by e–ν scattering at energies $\gtrsim 10$ MeV (because of interference from still other kinds of backgrounds at lower energies) using multi-tone water Čerenkov detectors. At least five of these are now operating and producing consistent results (T. Stanov, Bartol Research Foundation). The detector in Kamioka, Japan, however, has seen a considerable excess of low-energy neutrino-like events. If these result from stopped muons and the same flux hits the perchlorethylene tank, it will produce 0.37 ^{37}Ar per day, essentially the observed level.

An estimate of neutrino flux as a function of energy is vital for deciding whether the low flux at Homestake is due to a minor flaw in the solar model (affecting only the high-energy B^8 neutrinos), neutrino oscillations during propagation (which might reduce the flux at all energies by about a factor of three), or some major defect in modern astrophysical theory (for example, stars do not derive their energy from fusion and so do not produce any neutrinos at all). Apart from the Davis result, there are currently only upper limits, mostly several orders of magnitude above predicted values and pertaining to fluxes made by high-energy cosmic rays (P. Sokolsky, University of Utah) or stellar collapses (A. Burrows, SUNY) rather than by the Sun.

Contributions on the time-dependence of neutrino flux were rather more intriguing. Rowley's simultaneous plot of the ^{37}Ar production rate and sunspot numbers since 1970, particularly the coincidence of the very high run nos 27 and 71 with the giant flare of 4 August 1972 (another indicator of solar activity) strongly suggested a correlation. A. V. Kopylov (Institute for Nuclear Studies, Moscow) pointed out that the present data are not inconsistent with constant ^{37}Ar production rate, and R. Lingenfelter (University of California, San Diego) sketched out calculations eliminating the most obvious sort of connection: energetic particles from a large solar flare produce neutrino secondaries at a rate too low by 10^6 to affect the Homestake experiment. Nonetheless, the possibility of correlated time-dependence is clearly worthy of further study. It is therefore particularly disturbing that the Brookhaven experiment will have to be wound down over the next fiscal year unless a new source of support is found.

Several promising experiments are under construction. The Institute for Nuclear Studies, Moscow (N.V. Gavrin, A.V. Kopylov) has 25 tonnes of gallium metal on hand, and more available, and a chamber ready and lined with iron and concrete shielding at 3,500 m depth at Baksan. The group hopes for construction in 1985 and counting in 1986. ^{71}Ga (ν, e) ^{71}Ge has a low enough threshold to see neutrinos from ordinary pp reactions. The same group is also working on both a scaled-up ^{37}Cl experiment (five times Davis's volume; the equipment is ready, but the chamber still needs to be dug) and ^{7}Li(ν, e)^{7}Be (for which they have tested recovery and counting techniques for a 12-litre tank and are ready to try 200 l). The Cl experiment should provide a high enough count rate to see any solar cycle variations unambiguously, and, with patience, annual ones, while the Li experiment is sensitive to CNO cycle and pep neutrinos, thus testing different details of nuclear and solar physics.

MPI Heidelberg (W. Hampel) intends to continue a gallium experiment, in the form of $GaCl_3$, despite Brookhaven's withdrawal from the collaboration. They have tested germanium recovery and counting in a 1.25 tonne tank and envisage a 30 tonne experiment at an existing European site. L.S. Peak (University of Sydney) reported that his group is about to install its first 10 tonne module of a projected 100 tonne water Cerenkov detector to look for a ν–e scattering at the Broken Hill mine. In practice, this is sensitive only to B^8 neutrinos, owing to high backgrounds at low energies, but it is otherwise totally different from the Cl experiment and can yield approximate directional information, separating the Sun from other sources.

Models of the solar interior designed to reduce the predicted neutrino flux are numerous and often rather *ad hoc*. G. Michaud (University of Montreal) and E. Schatzman (University of Nice) reviewed the effects of turbulent diffusion. If this provides a diffusion coefficient about 100 times that expected from ordinary molecular diffusion, then fresh hydrogen coming in reduces the necessary central temperature slightly and hence the predicted flux by about the requisite factor of three. Energy to drive the turbulence and mixing can be drawn from the build-up of burnable ^{3}He just outside the solar core (I. Roxburgh, University of London). One price paid is a 30 per cent increase in main-sequence lifetimes for low-mass stars, and thus some difficulty in interpreting the Hertzsprung–Russell diagrams of globular clusters. A partial compensation is a better understanding of lithium abundances on the surface of old stars.

Efforts to probe the central temperature, composition, rotation and magnetic field distribution (all of which can affect neutrino production) of the solar interior using frequencies of *g*-mode oscillations would seem premature. G. Isaak (University of Birmingham), whose group has collected much of the solar surface velocity data concerned, does not believe that these modes have yet been unambiguously identified. The *p*-modes have been seen in considerable detail, but are only informative about the solar core after the dominant contributions from the envelope have been understood and subtracted.

Nonetheless, *p*-modes may already have

resolved one uncertainty. P. Gilman (High Altitude Observatory) reviewed the discrepancy between solar dynamo models with driving in the convection zone and models for convective driving of the solar differential rotation. The former require angular frequency to increase inwards (to make active zones migrate to lower latitudes through the solar cycle), while the latter require angular frequency to decrease inwards. The observed *p*-mode-splitting strongly favours ω decreasing inwards (see Duvall, T.L. Jr *et al. Nature* **310**, 22; 1984). Gilman suggested an alternative site for dynamo driving at the base of the convection zone, where ω seems to be rising again with depth.

Finally, P. Foukal (Atmospheric and Environmental Research Inc.) showed fragmentary sunspot, auroral and ^{14}C data suggestive of a roughly 11 yr solar activity cycle for several hundred years before the late-seventeenth-century turn-off (the Maunder minimum). And, in what was perhaps the greatest surprise of the meeting, he showed photographs of a pre-Cambrian varve sequence discovered by George Williams of Broken Hill Proprietary. Varves are layers deposited in periglacial lakes when rapid spring–summer melting and sediment transport alternate with quiet winter settling of silt. The annual layers showed additional banding with periods ranging from 9 to 14 yr and averaging 11.2 yr over a 20,000 yr sequence. This strongly suggests an influence by the solar cycle some 700,000,000 yr ago. There's nothing quite like real data, but you can never be sure where it's going to come from. ☐

Invertebrate neurophysiology

Sodium channels in muscle

from P.R. Stanfield

INFORMATION in the nerve fibres of both vertebrates and invertebrates is signalled by means of action potentials that are generated by an inward movement of sodium ions through channels (Na channels) which are selective and dependent upon membrane potential. Similar channels characterize most of the skeletal muscle fibres of vertebrates, where the all-or-nothing action potentials they produce trigger contraction by releasing calcium ions from an intracellular store in the sarcoplasmic reticulum. In contrast, invertebrate muscles have seemed to lack sodium channels, showing instead an electrical excitability that depends on the presence of calcium channels in the muscle fibre membrane and is either graded or all-or-nothing in nature. This calcium-dependent pattern of electrical excitability has been seen as phylogenetically older than the pattern in vertebrate muscle and Ca channels are themselves believed to be evolutionarily older than Na channels[1].

The generalization that invertebrate muscles lack Na channels has recently been challenged by Lawrence Schwartz and Walter Stühmer[2], who have used electrophysiological techniques to show that the striated muscle fibres of the planktonic arrow worm, *Sagitta elegans*, possess Na channels and certain other properties that make them very like skeletal muscle fibres of vertebrates. *Sagitta* was chosen because it belongs to the phylum Chaetognatha and in turn to the deuterostome branch of coelomate animals, the branch to which the vertebrates also belong.

In discussing their data, Schwartz and Stühmer argue that, since Na action potentials are always more rapid events than those depending on Ca^{2+}, they permit a more rapid switching on and off of muscle activation. The advantages of a rapid switch may have provided part of the selection pressure that led to the expression of Na-channels in muscle as well as in nerve. The rapid muscular responses required of a successful predator like *Sagitta* may account for its adoption of Na channels. The alternative, however, is that they are the bequest of an evolutionary ancestry shared with the chordates, and that the Na action potential in muscle is a deuterostome trait.

If this is a deuterostome trait, it is not a universal property among the group, nor is it limited to them. Indeed, since Na channels of very consistent properties are almost universal in nerve, it is possible that their expression in muscle has arisen independently in a number of groups. Thus, the tunicates (urochordates) lack muscle Na channels, while *Amphioxus* (among the cephalochordates) possesses them; these protochordates have therefore been seen as transitional between non-chordates that lack muscle Na channels and the vertebrates[1]. Furthermore, among the vertebrates, lack of Na channels lives on in smooth muscle and also in the slowly-contracting tonic skeletal muscle fibres, found in frog and, for example, in the extraocular muscles of certain mammals. Moreover, protostomes (the other branch of the coelomates) can also have muscle Na channels, for these have now been demonstrated in an evolutionary ancient group of arthropods, the scorpions[3].

While muscle fibres of the scorpion and of *Sagitta* both give brisk twitch-like contractions in response to Na-dependent action potentials, they are very different in other ways. First, in scorpion, the Na action potential is followed by a brief train of Ca-dependent ones[3], an electrical behaviour that has not been described in other muscles. Second, blockage of Ca channels or removal of external Ca^{2+} blocks contraction in the scorpion, in spite of the presence of a well-developed cellular store of Ca^{2+}. This dependence on external Ca^{2+} is commonly found in invertebrate muscles that lack Na channels. In *Sagitta*, as in vertebrate muscle, removal of external Ca^{2+} seems not to block contraction[2].

The presence of Na-channels in scorpion muscle may raise the question of whether Ca-dependent excitability really is the older form. There remains little doubt that it is, and arguments from ontogeny support the position. During development, vertebrate muscles go through a stage where they possess only Ca action potentials. And even in adult muscle, Ca channels are retained at a high density. In addition, in the tunicates, whose muscles lack Na channels, these channels are lacking in all cells in the initial stages of development (though they are present in the unfertilized egg) and are never expressed in presumptive muscle cells. Indeed, these cells acquire their mature pattern of ionic permeability very early in embryonic life, and at much the same stage at which Na channels first appear in presumptive nerve cells[4].

To confuse the picture, certain muscle fibres seem to have the potential but not usually the stimulus to express Na channels. Thus denervation of tonic muscle fibres of the frog leads to the development of Na action potentials; since reinnervation suppresses them again, some trophic effect of nerve seems to be involved[5]. Denervation of crayfish muscle has similar results[6].

At the end of their article, Schwartz and Stühmer challenge comparative physiologists to use new methods to investigate muscle cells hitherto inaccessible to electrophysiological attack. Since it was in a crustacean muscle that the first evidence for the Ca channel was obtained[7], since the pattern of evolution of muscle excitability turns out to be complex, and since a comparative approach will help sort out the poorly understood problem of excitation–contraction coupling[3], there is a strong case for a wide survey. ☐

The nature of tumour cell proliferation

SIR — The comments by Erika Coward[1] on the origins of malignancy were interesting though not entirely novel. Clearly, cancer is not just a matter of abnormal proliferation and it would seem necessary to invoke lesions which do more than alter the levels of regulators otherwise one would merely have hyperplasia. Nevertheless, it is equally evident that the major, and possibly only, defect which is common to all transformed cells is that they replicate when they should not do so. Such an effect can be induced in a variety of ways, each of which could produce a unique functional change, while operating through the same mechanism[2]. The ability to totally inhibit proliferation would be a major advance but it might not overcome the effects of the altered properties, for example, increased hormone production.

Bell[3], has considered some aspects of altered proliferation consequent upon changes in the levels of regulators, both inhibitory and nitrogenic. On the other hand, as a result of my deliberations on the nature of proliferation processes[2,4], I have suggested[5,6] that the aberrant behaviour of cancer cells in most cases is due to an altered threshold with respect to regulator levels — decreased with respect to mitogens, raised for inhibitors. (A threshold is required by the cell cycle concept I have developed[2,5], although it may vary in magnitude and can be zero in particular instances. Its existence provides an explanation for cell density inhibition of proliferation while an altered threshold accounts for the often observed effect thereon of the malignant transformation, namely the ability of such cells to attain much higher densities[5].) At the same time, I also briefly considered the effects of altered levels of regulators on surrounding normal tissue cells[5].

There is no evidence that tumour cells in general proliferate faster than the corresponding normal cells. However, although taking different approaches, both Bell and I concluded that a critical tumour size might exist above which the growth may increase more rapidly than hitherto (one possible explanation for latency). My studies[5] also indicated the possibility that tumours of limited growth potential might arise as a result of lesions which increase the uptake[7] or binding of regulators, whereas those affecting thresholds could (depending on the magnitude of the change) yield tumours more malignant with respect to growth potential.

A question of major importance to Coward's considerations, however, is whether or not regulation *in vivo* is ever effected by a single agent. Culture studies clearly indicate that the replicative ability of cells can be affected by a wide range of normal agents, including various hormones. Recent studies have emphasized that transformation is often associated with positive growth factors (mitogens) rather than inhibitors. I have proposed a mechanism for the interaction of regulators[2] and, on that basis, suggested[6] (in contrast to the chalone approach) that attempts be made to control the proliferation of tumour cells by the use of a combination of such agents rather than just one (thereby limiting side effects on the replication of normal cells). However, the available data fail to indicate which regulators should be used, and at what concentrations, in any particular instance. It would thus still seem necessary to establish suitable regimes by trial and error, as is the usual procedure.

Another problem is that of heterogeneity in the cells of a tumour. Such heterogeneity implies that the response to growth regulators will also be heterogeneous[5]. As a consequence, treatment by the methods proposed by Coward and by myself, are likely to meet the same limitations in this direction as present approaches. On the other hand, they may be less toxic for the patient and might not produce the opposing adaptive responses.

Interestingly, accompanying Coward's letter was another by Schleifer *et al.*[8] on the effects of psychological factors on the immune response. That brings to mind the old issue of whether or not the mental state can affect tumour formation and development, a topic about which there has been much (often subjective) discussion. There is much data showing that various hormones can regulate cell proliferation, both negatively and positively. It thus seems reasonable to accept that any process modulating hormonal levels, such as stress, is potentially able to modify tumour growth rate (if not transformation), although the actual dependencies are likely to be complex and individualistic.

Machine-readable DNA sequences

SIR — Hayashi and Munakata[1] suggest that the four bases in DNA might be represented by four musical notes. We prefer a graphic representation, where the four bases are displayed in a line extension format: values attributed to the four bases G,A,T and C being +2, +1, -1 and -2. In the example (below), 100 nucleotides of coding sequence from a recent paper[2] have been converted into this format: significant features of the sequence ("TATA" transcription signal — in fact TATTAT here; start site of transcription; translation initiation codon ATG) are indicated.

Such a presentation has several interesting features. First, particular sequence patterns are readily discernible: purine (A,G) rich stretches appear exclusively above the line and pyrimidine (C, T) stretches below. G/C and A/T rich regions have extended and retracted aspects respectively. Second, restriction sites appear (usually) as simple rotationally-symmetrical patterns which are rapidly picked out by the eye. Third, it takes little time to determine, for instance, that the dinucleotide pair *C followed by G* is, as expected, depleted. Fourth, to convert to the complementary strand the diagram need only be rotated through the horizontal axis.

Such a line extension format is inherently machine-readable, and may permit suitably equipped readers to transfer sequences directly from the printed page to an information retrieval system.

Organizing centres for three-dimensional chemical waves

Arthur T. Winfree
Department of Biological Sciences, Purdue University, West Lafayette, Indiana 47907, USA
Steven H. Strogatz
Division of Applied Sciences, Harvard University, Cambridge, Massachusetts 02138, USA

Excitable media propagate periodic waves of chemical activity. In three dimensions, they resemble scrolls rotating about axes where reactions are not periodic. These axes close in rings which may be linked and knotted, in ways limited by an exclusion principle.

NONLINEAR waves are conspicuous in a variety of biologically and chemically excitable media. Waves of excitation propagate at uniform speed and mutually annihilate in collisions in the Belousov-Zhabotinsky reagent[1-8], in retinal[9] and cortical[10-12] nerve nets, where they may underlie neuromotor pathologies such as epilepsy, in heart muscle[13-16] where they are involved in life-threatening arrhythmias, and in aggregations of social amoebae[17-20] where they coordinate normal development. These waves commonly appear as involute spirals radiating from tiny rotating activity patterns, here called 'organizing centres'. In three-dimensional media, spirals are still seen, now as cross-sections through a scroll-shaped wave[3-5,21-28]. The scroll emanates from its central organizing axis, which typically forms a closed ring. The simplest form of organizing centre is an 'untwisted scroll ring'[1-4,21-28] or 'toroidal vortex'[29]. We present here a chemical/topological exclusion principle that predicts a quantized hierarchy of other, topologically distinct organizing centres and delimits the initial conditions required for their experimental realization[22-28]. We now review the published theoretical, computational, and experimental evidence concerning these three-dimensional reaction-diffusion structures.

Scroll rings

Periodicity is the central principle of all these arrangements of waves. Throughout any region organized by a spiral wave (Fig. 1), each point cycles periodically through activity, refractoriness, quiescence, and activity again. Hence we may describe a snapshot of the pattern in terms of the spatial distribution of phase. The phase, ϕ, of a point means the fraction of a cycle elapsed since the last wavefront excited that point. We represent the phase geometrically as a point on an abstract cycle, the unit circle S^1.

Description of spiral patterns in terms of phase entails a weird topological consequence: there must be a 'phase singularity' in the medium[1-3,23,30]. To prove this, first consider any closed path C enclosing the spiral's inner portions (Fig. 2). In one circuit of C, phase changes through exactly one full cycle. In mathematical terms[1,31], the map $\phi|_C: C \rightarrow S^1$ has winding number $W = \pm 1$. To conclude the proof, a theorem of topology[31] asserts that since $W \neq 0$, phase cannot be assigned continuously throughout any disk bounded by C. The most localized discontinuity possible is a phaseless point surrounded by all phases of the cycle: a phase singularity. The immediate neighbourhood of the singularity is a rotating pattern of chemical activities, the pivot of the rotating spiral wave, and the centre from which it radiates.

Because even a thin layer of excitable medium has finite thickness, the ostensibly flat spiral is actually a cross-section of a three-dimensional wave shaped like a scroll. This wave emerges from a filament of singularity. The filament has no physical substance; it cannot be strained out of the liquid like a strand of spaghetti. It represents merely the locus of intersection between two surfaces of uniform chemical concentration[1,3,21-23]. As such, it typically closes in a ring (unless interrupted by the physical boundaries of the medium as in Fig. 2). This predicted exact closure was confirmed experimentally by reconstruction of the fixed wave from serial sections[28,32] and by recent direct video recording during the uninterrupted reaction[4], as well as by computer simulation from the equations of local kinetics and molecular diffusion[3,29]. In the Belousov-Zhabotinsky reagent, these scroll rings persist through about a hundred rotations of the scroll, shrinking slowly at a rate which increases with the curvature of the singular filament[4,21,29,32].

A symmetric caricature of the observed scroll ring is shown in Fig. 3*a*, which depicts a snapshot of the expanding wavefront of excitation. In the next instant, the front would advance a uniform distance at every point and the ring would shrink slightly.

Twists and links

New topologically distinct possibilities exist for scroll ring closure. Imagine forming the ring by bending a straight segment of scroll, then sealing its ends together to preserve continuity (Fig. 3*b*). We might instead have given the straight scroll a 360° twist (Fig. 3*c*), or even have tied knots in it before joining its ends. These structures are indistinguishable locally: in each, a short segment along the singular filament is indistinguishable from a segment of the scroll ring of Fig. 3*a*. Because that untwisted, unknotted scroll ring is viable, local considerations suggest that twisted and knotted rings might be comparably stable.

However, global topology forbids most of these otherwise-plausible organizing centres. Consider, for example, the once-twisted scroll ring (built on the pattern of Fig. 3*c*) that has evolved to fill a cube of the medium. The winding number argument used above to detect a singularity reveals that this solitary once-twisted ring cannot exist: it must be threaded by another singular filament. To prove this, we evaluate the winding number along the inner equator of the invisible torus that confines Fig. 3*b* and *c*. As shown in Fig. 4, W is the number of twists locked into the planar scroll ring. Because $W \neq 0$, any surface bounded by that equator must be punctured by a singular filament[1,24,31].

In a computer-generated image[24,27,28] of the fully evolved wave (Fig. 3*d*), spirals emanate from the singular ring and collide awkwardly along a gnarled helicoidal surface, whose axis is the topologically-inferred phase singularity. This image was constructed by placing an involute spiral in each half-plane extending radially from the ring's axle, and then twisting it through 360° while swinging the plane once about the axle. Gomatam[5] has also shown analytically that such a screw

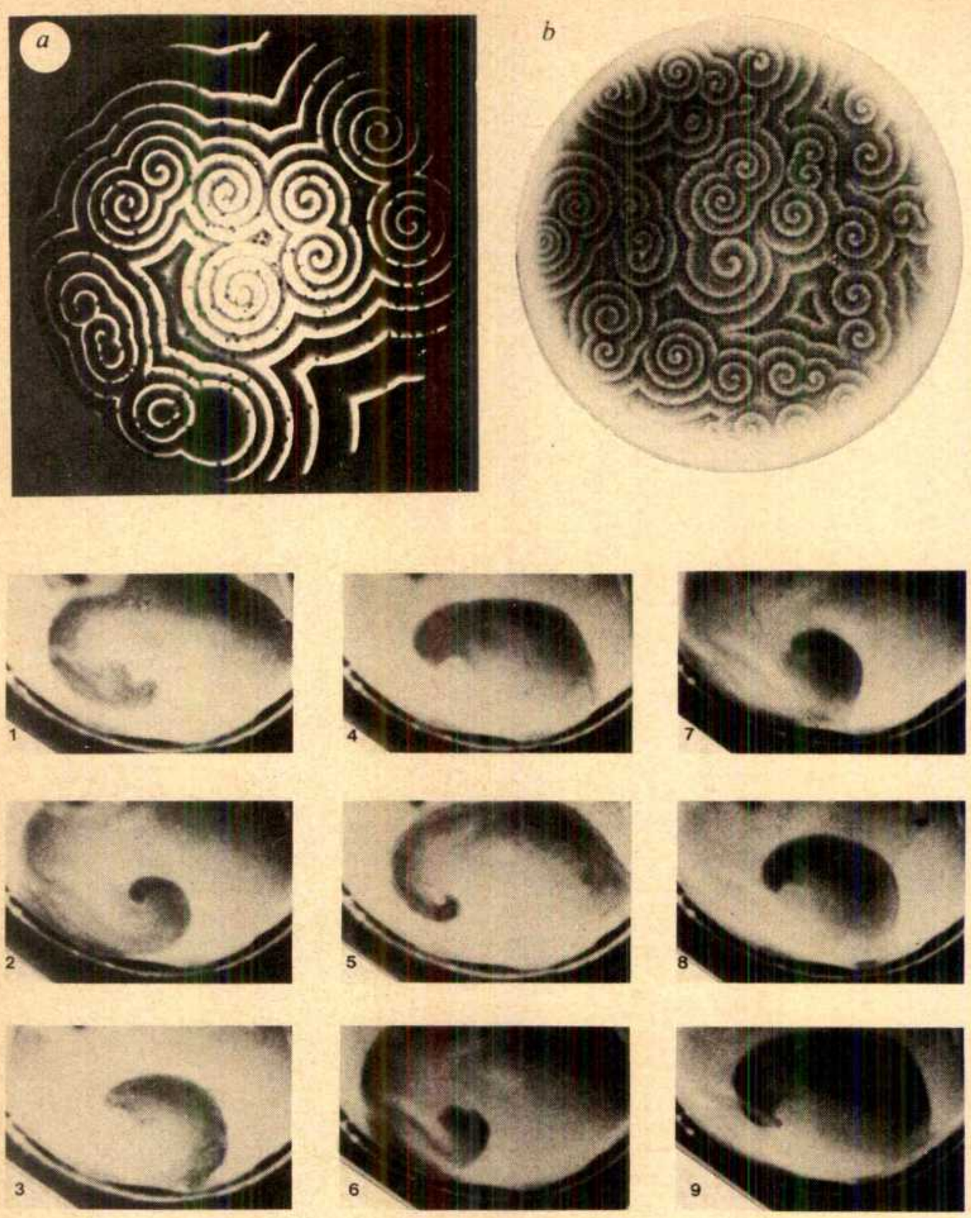

Fig. 1 Rotating spiral waves in excitable media. *a*, Transmitted light photograph of the chemical reagent originated by Belousov[42], and modified[2,7,21]. Waves radiate from spiral centres at a few mm min^{-1}, the spirals turning in about 1 min. The liquid layer is 1 mm deep; the field of view spans 90 mm. *b*, Dark-field photograph of a monolayer of *Dictyostelium discoideum* cells. Cells refract light differently when responding to a pulse of cyclic adenosine monophosphate. The instantaneous loci of this response are spirals rotating once in ~5 min as waves propagate at a few mm min^{-1}. The field of view spans 90 mm (with permission from Newell[20]). *c*, Successive photographs of the retina of a chicken taken by ambient light at intervals of 40 s. The dark area consists of cells recovering behind a wavefront of spreading depression. The front moves ~3 mm min^{-1}, rotating once in 3 min (twice in this mosaic). The field of view is 11 mm × 7.5 mm. (Adapted with permission from Gorelova and Bures[9]).

surface is a solution to linearized reaction–diffusion equations. Because physical rotation is equivalent to time evolution for this particular solution[24], we can animate the intricately rotating, propagating, and self-colliding wavefront by merely spinning it about its vertical axle (ref. 28, and our videotape).

However, there are two reasons why this symmetric solution is best regarded as a limiting extreme of a physically more realistic case. First, observation shows that stable spiral waves in excitable media always radiate outwards from their singularity; here they have been allowed to converge to the axial singularity in Fig. 3*d*. Second, to avoid ending the wave along an unphysical edge, the symmetries of Fig. 3*d* require it to extend to infinity in all directions, in violation of the realistic requirement that waves propagate at finite speed.

The practically realizable (but analytically less convenient) alternative is a pair of identical linked twisted scroll rings. Each provides the necessary threading singularity for the other. Figure 5*a* represents this organizing centre with the horizontal ring viewed nearly edge-on, while the other, regarded as arbitrarily large, is vertical, but hidden behind an interface where waves from each source collide. In Fig. 5*a*, viewports are opened in the horizontal scroll wave as it approaches collision a finite distance from the much larger vertical source ring. Realism is improved in Fig. 5*b* by giving both rings identical radii. Figure 5*b* presents a schematic of comparably sized rings, interlinked by their mutual rotation.

This mated pair of linked scroll rings exists in two mirror-image isomers, each with both singularities left-twisted (as here) or right-twisted. Either can be constructed from toroidal surfaces of uniform chemical concentration[23,24]. Experimental methods to contrive such initial conditions in an excitable medium are suggested elsewhere[23,24]. If its laboratory synthesis is successful the pair of linked twists will be the second observed organizing centre.

Exclusion principle

The allowed anatomy of an organizing centre is quantized by an exclusion principle, derived from both chemical and topological requirements. Away from boundaries of the medium, surfaces of uniform concentration must be disjoint, closed, and orientable; infinite concentration gradients are forbidden; singular filaments must be wave sources, not sinks; and far from the organizing centre, concentrations must approach quiescent uniformity[23]. The exclusion principle then states[26] that any realizable organizing centre must satisfy the constraints that:

$$\sum_{j=1}^{R} L_{ij}N_j = 0 \text{ for each } i = 1, 2, \ldots, R \qquad (1)$$

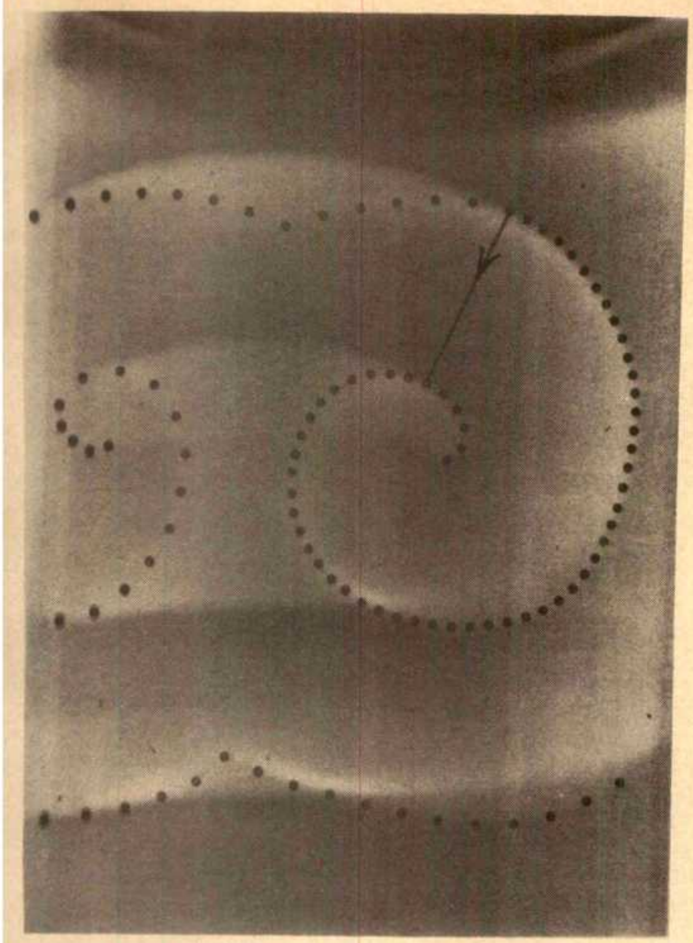

Fig. 2 Untwisted scroll wave and singular filament. A scroll wave in modified[4] Belousov–Zhabotinsky reagent is outlined in dots added to the photograph. Its spiral cross-section is exposed where it encounters the glass wall. A closed curve is traced 360° along this spiral with no change of phase (the chain of closely-spaced dots) then radially through one full wave (the line segment) passing through one full cycle of phase. It is accordingly linked by a singular filament: the scroll's source. (Reproduced with permission from Welsh *et al.*[4].)

where R is the number of constituent rings or knots[25], N_j is the positive number of spiral arms emanating from ring j (the singularity's "topological charge"[6]), L_{ij} is the linking number of rings i and j, and L_{ii} is the linking number of ring i with an imaginary ring traced along the wavefront infinitesimally nearby. These equations dictate the unique integer number L_{ii} of revolutions of the spiral wave required along each ring: $N_i L_{ii}$ must be equal and opposite to the sum of that ring's signed linkages with each of the other rings, counted with multiplicities N_j. L_{ii} is a sum of two real numbers called[25,33,34] the 'twist' (an integral of the spiral's gyration around the ring) and the 'writhing' (which depends only on the shape of the filament itself, and is zero for planar rings).

For a solitary ($R = 1$) ring or knot, the principle requires $L_{ii} = 0$. Thus, it predicts that a solitary scroll ring cannot contain net twist, as proved earlier by winding number arguments, and a solitary scroll knot must be twisted by an amount equal and opposite to its writhing number[25,26,34]. An untwisted ring pair cannot link. A pair of rings may contain equal twists if appropriately linked. For organizing centres composed of more than one ring, equation (1) specifies the set of quantum numbers, N_j, L_{ij}, and L_{ii} compatible with the known constraints. There may be additional constraints forbidding some organizing centres allowed by equation (1).

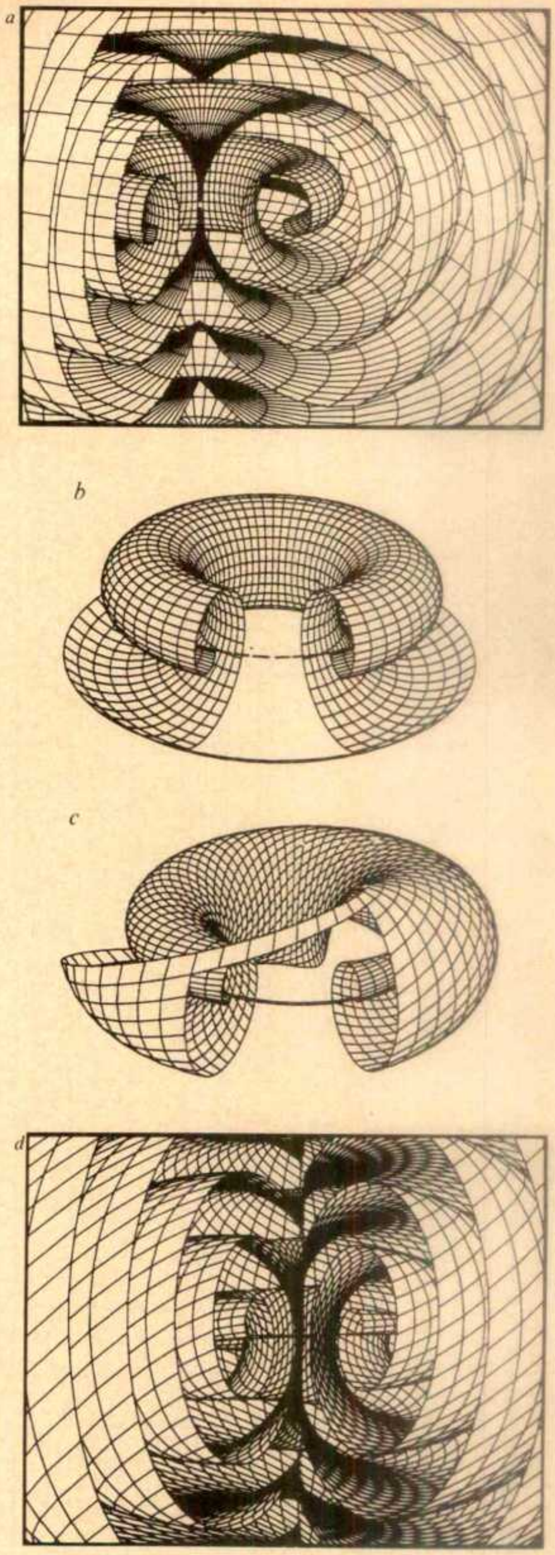

Fig. 3 Computer images of untwisted and twisted scroll rings. *a*, The inner lamina of an untwisted scroll ring wave fill the field of view. Their source is a horizontal circle of phase singularity, the front's inner edge. To aid in visualization, wavefronts are made transparent within a wide sector reaching to the internal symmetry axis along which wavefronts collide. (Reproduced from ref. 28.) *b*, At the same scale, we show as much of *a* as fits inside a torus around the singular ring. The wave's edge is a closed ring. *c*, As in *b* but the contents of the invisible torus are given one full 360° left twist around the circumference. The outer edge of this wave (where it terminates on striking the torus) is still a closed ring, but it now links the torus. *d*, As in *a*, but the wave field is extrapolated from *c* rather than from *b* to fill space. A phase singularity linking the torus is unavoidable. Here it is depicted as the unphysical focus of converging waves. (Reproduced from ref. 28.)

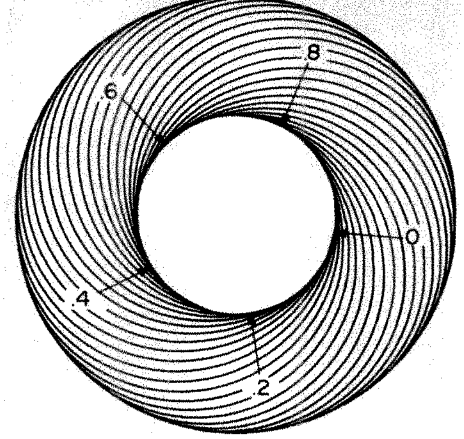

Fig. 4 Successive wavefront positions on a twisted scroll ring. Closed contours of fixed phase on an imaginary toroidal shell enclosing a uniformly once-twisted scroll ring. Only half of each contour is visible. A disk plugging the hole in the toroid touches these phase contours in serial order, spanning one cycle around the disk's boundary. Since $W \neq 0$, the disk must contain a phase singularity[31]. Applying the same argument to every diaphragm bounded by the toroid's inner equator, we detect an unforeseen singular filament threading the twisted scroll ring[1,24].

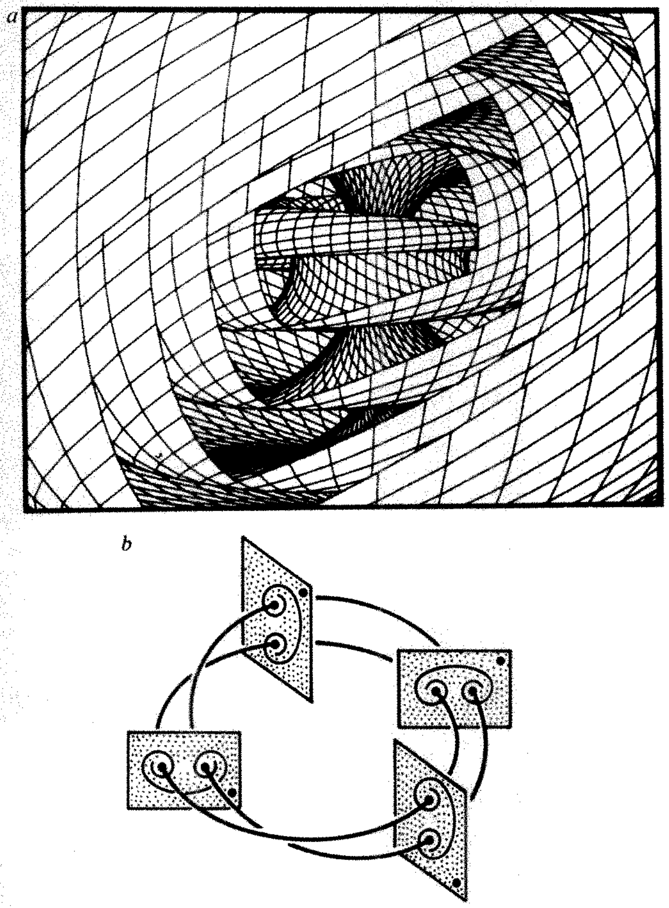

Fig. 5 Mutually linked pair of left-twisted scroll rings. *a*, As in Fig. 3*d*, a once-twisted scroll wave radiates from a horizontal source ring (exposed through a succession of windows). But here the wavefront stops short of collision with itself along an unphysical 'sink'. Rather, it collides with the outgoing wave from the much larger vertical twisted scroll ring hidden in the interior. (Reproduced from ref. 28.) *b*, A mirror-image pair of spirals is transported around a circular path to sweep out a pair of adjacent scrolls. Four local cross-section planes are shown. The pair is rotated as it is transported, so that each scroll is left twisted and the two are mutually linked. Waves emerging from the pair in each cross-section plane eventually join in rings. (Reproduced from ref. 24.)

Transmutation

Solitary scroll rings tend to contract towards their centres of curvature[4,21,29]; it seems likely that the twisted rings of more complex organizing centres do the same. Unless neighbouring filaments repel one another[22], organizing centres in media without boundaries must then eventually decay, leaving behind only quiescent uniformity. (Assuming that there are boundaries, a ring retains the alternative of opening into a scroll wave with an uncurved and stable axis.) Elementary decay processes[3,21] can only involve fission or fusion of rings. It is possible to envision such events in terms of continuous deformation of concentration fields[26]. The result in each case is a rearrangement of quantum numbers which alters R by ±1 and preserves identities (equation (1)). One allowable transmutation pathway regresses from a solitary trefoil knot to a linked pair of twisted scroll rings to a solitary untwisted scroll ring to an unlinked pair of scroll rings or to spatial homogeneity ('vacuum'). The latter two transmutations have already been observed in a chemically-active medium[37]. Presumably they can also occur in reverse, including the final transmutation to/from the vacuum state. In particular, mechanisms for creating scroll rings *ex nihilo* may have practical importance in biologically excitable media such as heart muscle[38].

Conclusion

We envisage a hierarchy of organizing centres ordered by the number of constituent rings. Loosely analogous to the Periodic Table, this hierarchy contains atoms made of scroll rings, much as in the "vortex atom" notion of Thomson and Helmholtz[39,40]. At each level, diverse isotopes are distinguished by mutual linkage and knotting of rings. Atomic structure is defined by integer quantum numbers, restricted by an exclusion principle. Fission and fusion transmute the elements. However, the geometric periodism peculiar to organizing centres imposes on them a more complex hierarchy than the rows and columns of the Periodic Table.

Attempts are under way to synthesize some of the missing organizing centres, and to observe organizing centres in diverse excitable media. Solitary scroll rings, at least, have been reported in chemically-active media[4,32] and in thick cardiac muscle[38].

Organizing centres could be biologically significant. They emit waves of short period comparable with the absolute minimum attainable, the medium's refractory period. Because waves mutually annihilate in collisions, higher frequency sources eventually dominate slower ones, including normal pacemaker centres, thus usurping control. Although modified by the inhomogeneities of biological media, such organizing centres may be involved with the pathological waves of spreading depression and epilepsy[9-12], and of cardiac fibrillation and sudden death[13-16,38,41].

India–Eurasia collision chronology has implications for crustal shortening and driving mechanism of plates

Philippe Patriat & José Achache

Institut de Physique du Globe de Paris, Université Paris 6, Laboratoire de Géomagnétisme et Paléomagnétisme, 4 Place Jussieu, 75005 Paris, France

The motion of the Indian plate is determined in an absolute frame of reference and compared with the position of the southern margin of Eurasia deduced from palaeomagnetic data in Tibet. The 2,600 ± 900 km of continental crust shortening observed is shown to have occurred in three different episodes: subduction of continental crust, intracontinental thrusting and internal deformation, and lateral extrusion. The detailed chronology of the collision and plate reorganizations in the Indian and Pacific oceans supports the hypothesis that slab-pull is a dominant driving mechanism of plate tectonics.

THE collision between the Indian and Eurasian continents is considered to be one of the major tectonic events of Cenozoic time. It has resulted in ~2,000 km of north–south crustal shortening within continental Eurasia[1]. Several models have been proposed for the mechanism of this shortening: continuous deformation, multiple continental underthrusting, eastward propagating extrusion or mosaic tectonics[2–5]. Convergent plate motion still occurs between India and Eurasia and is evidenced in particular by active tectonics beneath the Himalayas, in Tibet and in south-central Asia[6–8].

The continental effects of the collision have been extensively studied, in particular during the 1980–83 French–Chinese cooperation programme in Tibet[5–9]. Geological or geophysical observations on land can only give bounds on the age of the initial collision. For instance, structural observations along the Yarlung Zangbo suture zone (YZSZ) in Tibet (in the vicinity of Lhasa) show the ophiolites to have been obducted before the end of the Eocene (before 40 Myr)[9]. Such a young upper bound is also indicated by petrological and geochronological data on igneous rocks in Tibet. Indeed, the youngest granodiorites observed near Lhasa are dated at 41 Myr (ref. 10) and thus may be consistent with the subduction of oceanic crust beneath Tibet until at least 45 Myr, assuming up to 4 Myr for the transit and cooling of magma in the crust. An older age for the initial collision has been proposed from geological evidence and seafloor spreading data[11]. It is suggested that it began, at least in the Ladakh area, before the middle Eocene (near 53 Myr).

On the other hand, only a few studies have analysed the consequences of the collision on plate tectonics. In an early analysis of seafloor spreading in the Indian ocean, Molnar and Tapponnier[12] interpreted a decrease in the rate of northward drift of India near 40 Myr as indicative of the India–Eurasia collision. Using more detailed data, this slowing of the Indian plate has been associated with the decrease in spreading rate on the Eastern Indian ridge near anomaly 22 time (~50 Myr)[13–15]. Following Molnar and Tapponnier[12], several authors have related this change in spreading rate to the collision between the two continental masses[16,17]. However, the change in India–Africa relative motion observed at anomaly 20 (44 Myr) has been considered elsewhere as indicative of this collision[17]. Also, evidence for an important plate reorganization in the north-eastern Indian Ocean after anomaly 20 time has recently been put forward and interpreted as a consequence of the collision[18].

Here we use a more comprehensive set of marine magnetic anomalies in the central Indian Ocean, in the vicinity of the triple junction[19] to determine the detailed motion of the Indian plate since anomaly 32 time (late Upper Cretaceous) and to clarify the chronology of the collision. The relative position of India with respect to Eurasia is computed using a procedure originally proposed by Patriat *et al.*[17]. It is then compared with its absolute position with respect to the hotspot frame of reference. This latter absolute motion is compared with recently determined palaeomagnetic poles in Ladakh, Tibet and Thailand[1,20–22] in order to determine the northern extent of India before the collision. The present data are combined with a recent interpretation of the northeastern Indian Ocean[18] to provide a complete reconstruction of the Indian plate before, and immediately after, the India–Eurasia continental collision. The relative importance of the driving forces of plate tectonics is then discussed taking into account these reconstructions.

Age of the India–Eurasia collision

In the past 15 yr, an extensive survey has been performed in the Indian Ocean using ships *Gallieni* and *Marion Dufresne* (see ref. 23). This survey has allowed a detailed interpretation of marine magnetic anomalies in the Central Indian Basin, the Crozet Basin and the Madagascar Basin[19,23] (Fig. 4*b*). These anomalies were generated at the accreting boundaries between the India, Antarctica and Africa plates, which meet at the Rodriguez triple junction. The simultaneous study of seafloor spreading on both flanks of these three ridges in the vicinity of the triple junction has allowed a complete and consistent

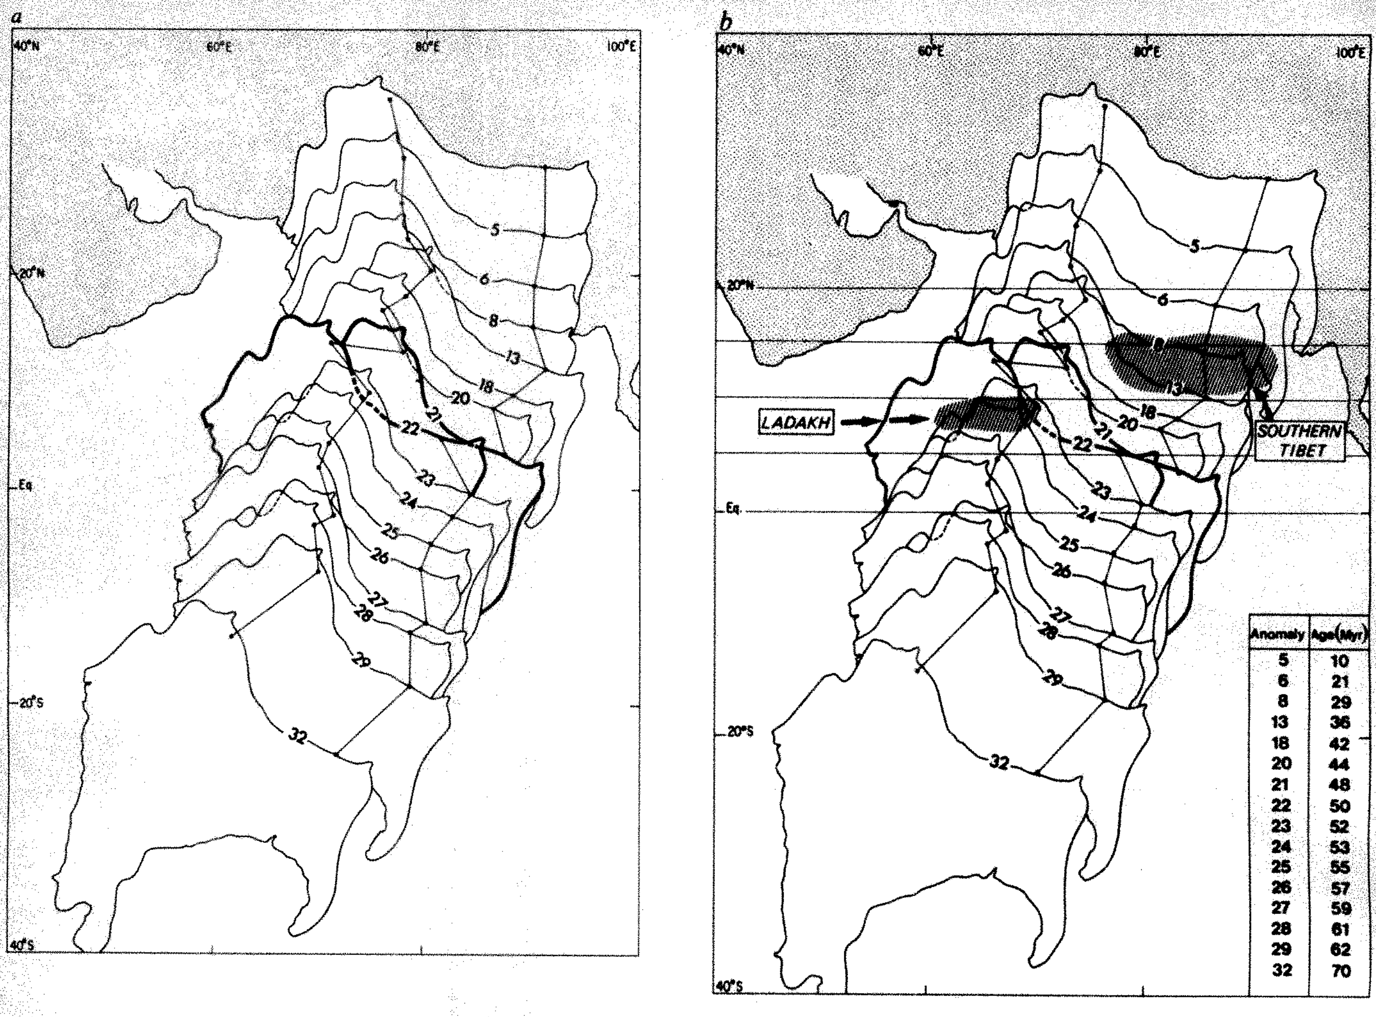

Fig. 1 Cenozoic northward drift of India. The northern limit of the Indian continent is taken as the present position of the Indus–YZSZ. The passive margins are drawn at the 500-m isobath (represented at anomaly 32 time). Also plotted is the motion of two points located on the Indian continent near the northern margin: in Ladakh (34°34′ N, 76°7′ E) and on the suture zone near the present position of Lhasa (29°20′ N, 91° E). The position of the northern margin of India is emphasized at the time of initial collision with the southern margin of Eurasia (anomalies 22 and 21). *a*, Relative motion of India with respect to Eurasia, kept arbitrarily fixed in its present position. *b*, Absolute motion of India in the hotspot frame of reference. The positions of southern Tibet and Ladakh before collision deduced from palaeomagnetic data, are also indicated for comparison.

reconstruction of the relative motion of the plates from anomaly 34 time (83 Myr) to the present[19].

Figure 1*a* represents the successive positions of India since anomaly 32 time (70 Myr) with respect to the Eurasian plate which is kept arbitrarily fixed in its present position (Table 1). The position of India at a given time is obtained by combining the rotation of India with respect to Africa, determined from magnetic anomalies in the Indian Ocean[19], with the rotation of Africa with respect to Eurasia, deduced from magnetic anomalies in the Atlantic Ocean[24–26]. Figure 1*b* shows the successive positions of India with respect to the hotspot frame of reference (Table 2). Here, India is, as before, first restored in its position with respect to Africa but then Africa is rotated in its position with respect to the hotspot reference frame at a given time[27].

The two reconstructions of Fig. 1 are very similar. It confirms that during the Cenozoic, the Eurasian plate underwent only a small clockwise rotation with respect to the Earth's mantle. This is evidenced by the apparent polar wander path (APWP) of this plate between 60 Myr and the present[28–30] and also by hotspot tracks analysis[27]. In addition, the location of the Euler pole for this rotation implies very little latitudinal displacement of the plate in the vicinity of the collision zone[1,30].

One can observe on Fig. 1 three successive phases in the drift history of India. First, down to anomaly 23 (52 Myr) India was drifting northward with a mean velocity of 15 to 20 cm yr^{-1}. Then, between anomaly 23 and anomaly 13 (36 Myr) the motion of India became rather erratic showing several changes in direction while the mean northward velocity was reduced to <10 cm yr^{-1}. Finally, from anomaly 13 to the present, India resumed a stable northward direction of convergence with respect to Eurasia with a constant rate of <5 cm yr^{-1}.

The decrease of the mean velocity of India is seen in Fig. 2 where the rate of convergence between India and Eurasia is computed at two arbitrary points and plotted as a function of time, assuming two particular orientations of the plate boundary (subduction). Before anomaly 22 (50 Myr), the rate varied between 15 and 25 cm yr^{-1}; it then decreased until anomaly 18 (42 Myr) (or 13, depending on the orientation of the trench), where it reached a stable value of ~ 4 cm yr^{-1}.

The sudden velocity drop after anomaly 22 is more clearly observed directly on the evolution of spreading rates at the eastern and central Indian ridges (Fig. 3). Indeed, on both spreading centres bordering the Indian plate, one observes a sharp decrease in spreading rate between anomalies 22 and 21. On the central Indian ridge, the velocity decrease seems to have occurred slightly later in the vicinity of the Vema fracture zone (Fig. 3*a*). This should be atrributed to the uncertainties in the reconstruction of plate motion in this area, also suggested by the frequent changes in the azimuth of spreading near anomaly 22 time (Fig. 3*b*) and due to the proximity of the pole of rotation.

These changes in the direction of spreading coincide with the surprisingly erratic behaviour of India, indicated in Fig. 1, at the time of anomalies 22 and 21. The Indian plate seems to have

The rotation at A32 between India and Africa is obtained by combining the India–Antarctica and Antarctica–Africa rotations.

undergone, during this period, several successive important shifts in its direction of motion (absolute or relative to Eurasia). Since the momentum of a plate can always be neglected[31], such shifts must be explained by successive changes in the balance of forces applied to the plate. The time constant for these changes is too short to allow a significant modification of the body or surface forces acting on the entire plate like gravitational sliding (ridge-push) or viscous drag. Thus, the shifts observed should rather be related to modifications at the plate boundaries. Following earlier studies, we suggest that the directional shifts and velocity decrease of the Indian plate observed at anomalies 22 and 21 time are likely to be associated with the closure of the Neotethys to the north of India and thus to indicate the onset of the collision of India with the southern margin of Eurasia.

Reconstructions based on magnetic anomalies 22 and 21 on both sides of the central Indian ridge are subject to some uncertainties. However, anomaly 21 is also well identified on the two flanks of the eastern and western Indian ridges, and the rotation of India with respect to Africa determined on the central Indian ridge is in close agreement with the combined rotation of India with respect to Antarctica and of Antarctica with respect to Africa. This confirms that even when uncertainties are taken into account, the shifts in plate motion direction described above cannot be avoided in the reconstructions. Thus, although a precise description of the actual motion of India between anomalies 23 and 21 time cannot be achieved, the shifts observed must be considered as significant and indicative of a peculiar and major event, such as the beginning of a continental collision.

Palaeomagnetic data in Tibet

In Fig. 1*b*, the position of the northern margin of India in the hotspot frame of reference is compared with the palaeoposition of the southern margin of Eurasia deduced from palaeomagnetic studies. It has been shown that the two frames of reference used for this comparison, the axial geomagnetic dipole field and the hotspot frame, have remained fixed within 5°–10° of each other, in the past 60 Myr (refs 27, 29). Furthermore, the consistency between the palaeomagnetically-determined latitude of India and its absolute position derived from oceanic magnetic anomalies and hotspot track analysis is confirmed by recent palaeomagnetic work in Tibet, on the northern margin of India[22]. This study of Eocene limestones, sampled to the south of the YZSZ, reveals two different components of magnetization. A primary component of Lower Eocene age indicates a palaeolatitude for the northern margin of India, in the vicinity of Lhasa, of 2.5°±4° S. Our present reconstruction places the sampled area at anomaly 26 time (the age of the magnetization) at a palaeolatitude of about 6° S (Fig. 1*b*). A secondary post-collisional component is also revealed by the study of Besse *et al.*[22] and indicates a palaeolatitude of 6°±5° N. This is again very consistent with our reconstructions which show the collision to have occurred in the area of Lhasa near 5° N (Fig. 1*b*).

Two palaeomagnetic poles have been derived for southern Tibet in the area of Lhasa for late Cretaceous and Palaeocene time[1]. Southern Tibet was accreted to the southern margin of Eurasia before the late Jurassic[5] and, therefore, indicates the position of this margin since that time. The late Cretaceous pole, derived from Albian–Aptian red beds, places the margin near Lhasa at a palaeolatitude of 11.5±3° N. The early Cenozoic pole has a slightly larger confidence limit associated with the large timespan of volcanic emplacement (ages range at least

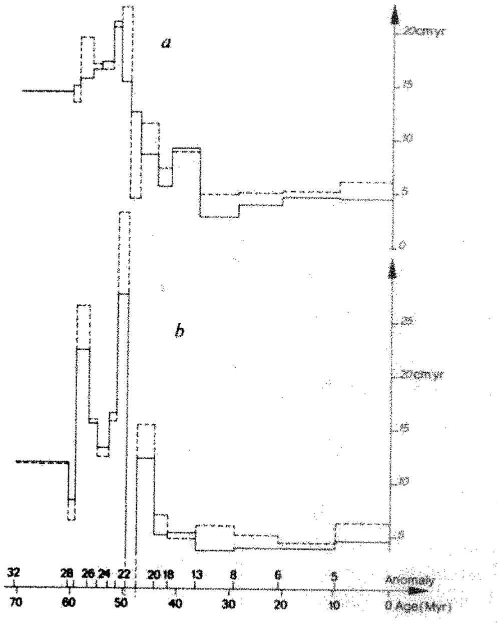

Fig. 2 Computed rate of convergence between the Indian and the Eurasian plates during the Cenozoic, at two arbitrary points (5° N, 75° E, solid line; 5° N, 90° E, dashed line) along two particular directions. It indicates the rate of subduction perpendicular to the trench for a subduction zone located near the southern margin of Eurasia and trending N120 E (*a*) or east–west (*b*).

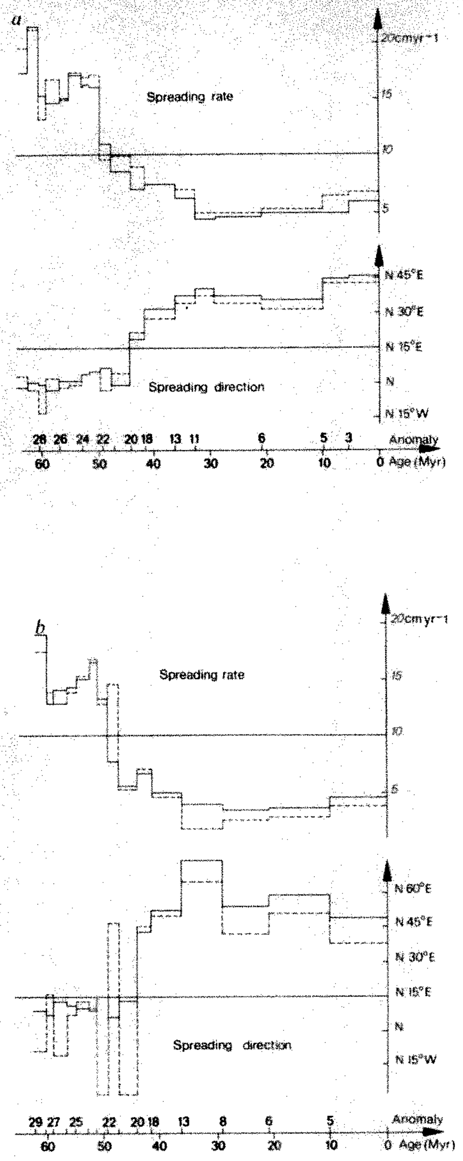

Fig. 3 Measured rate and direction of spreading at two accreting boundaries of the Indian plate during the Cenozoic. *a*, Eastern Indian ridge, in the vicinity of the Rodriguez triple junction (solid line) and near the Amsterdam fracture zone further east (dashed line). *b*, Central Indian ridge, in the vicinity of the triple junction (solid line) and near the Vema fracture zone further north (dashed line). The important shifts in spreading direction near the Vema fracture zone are related to the proximity of the reconstructed poles of rotation at the time of the collision (anomalies 22 and 21).

from 60 Myr (ref. 32) to 48 Myr (ref. 33)), secular variation of the Earth's magnetic field and the possible occurrence of Cenozoic deformation within southern Tibet[1,34]. This younger pole indicates a palaeolatitude of 13±6.5° N for the southern margin of Eurasia.

Another palaeomagnetic pole has been derived in Tibet, north of the Indus–YZSZ, for Palaeocene–Eocene time in the Ladakh area[20]. The Ladakh intrusives have been interpreted as the batholitic foundation of an island arc[35,36]. The remanent magnetization recorded in these intrusives indicates a palaeolatitude between 7 and 10° N and is considered to have been acquired shortly before 50 Myr.

It can be seen on Fig. 1*b* that the northern margin of India collided with the Ladakh island arc before anomaly 24 (53 Myr). It is not until anomaly 22 (50 Myr), however, that the first significant change in the direction of motion occurred on the Indian plate. This confirms that such a collision between a large continent and an offshore island arc is unlikely to significantly alter the motion of the plate.

In contrast, one observes on Fig. 1*b* that at anomaly 22 time, the northern margin of India near Lhasa still lay about 7° south of the southern margin of Eurasia (southern Tibet). Since Argand[37], several estimates of crustal shortening have been proposed for the Indian continent and accounted for, either by continental subduction beneath Tibet along the YZSZ, or by underthrusting within India (along the Main Central thrust (MCT), Main Boundary thrust (MBT) or Kangmar thrust. See, for example, refs 5, 38). The reconstruction proposed here implies between 400 and 1,000 km of continental shortening between India and southern Tibet, at the longitude of Lhasa. Uncertainties are taken from the position of India at anomalies 23 and 20 (see Fig. 1) and are thus likely to be overestimated.

Driving mechanism of plates

The analysis of seafloor spreading on the central and eastern Indian ridges reveals that the decrease in spreading rate at anomaly 22 is followed at anomaly 20 by a consistent and significant change in the direction of spreading (Fig. 3). A more detailed analysis of magnetic anomalies in the Central Indian Basin and the Crozet Basin reveals that this change in spreading direction did not occur synchronously along the entire eastern Indian ridge. Instead, the change seems to have propagated eastward along the ridge. Anomaly 20 is parallel to the new direction of spreading near the triple junction but is still parallel to older anomalies further east[19]. The change in spreading direction on the central Indian ridge was accompanied by a jump of the spreading centre. This is evidenced by the existence in the Madagascar Basin, near Ile Maurice, of a fossil spreading centre which ceased spreading just before anomaly 20 time[19].

Liu *et al.*[18] have re-analysed magnetic anomalies in the north-western Wharton Basin, south of Sumatra. They have recognized a fossil spreading centre. The existence of this fossil ridge was first reported by McDonald[39] who observed a series of basement highs beneath the sedimentary cover of the Nicobar Fan. This accreting plate boundary which separated India from Australia in the early Cenozoic, before the India–Eurasia collision, ceased its spreading shortly after anomaly 20 time[18].

Cande and Mutter[40] have re-identified the oldest magnetic lineations between Australia and Antarctica. They propose that initial rifting between the two continents took place between 110 and 90 Myr but seafloor spreading occurred at a very low rate of <1 cm yr^{-1} until anomaly 21, where it reached a value of 2 cm yr^{-1}. After anomaly 20, this spreading rate suddenly increased significantly to a value of 5.5 cm yr^{-1}.

All these observations indicate the occurrence of a global plate reorganization in the Indian Ocean which seems to have started near the Indian triple junction immediately before anomaly 20, near 45 Myr, and to have been completed before the formation of anomaly 19, near 43 Myr. Figure 4 represents the plate configuration in the Indian Ocean at anomaly 24 time (53 Myr), that is before the beginning of the collision (Fig. 4*a*), and at anomaly 18 time (42 Myr), when the plate reorganization had been completed (Fig. 4*b*). The reconstruction of the spreading centre between India and Australia is based on the new identification of magnetic anomalies in the Wharton Basin[18]. The central and western Indian Ocean are reconstructed from the identification of magnetic anomalies described in Patriat[19]. Finally, the whole reconstruction is rotated in an absolute position with respect to the hotspot frame of reference. This allows the comparison with palaeopositions deduced from palaeomagnetic studies.

The position of the southern margin of Eurasia is given by palaeomagnetic data in Tibet (see above) and Thailand. Mesozoic poles for the Indochina block indicate an early Tertiary palaeolatitude for this block between 15 and 20° N (ref.

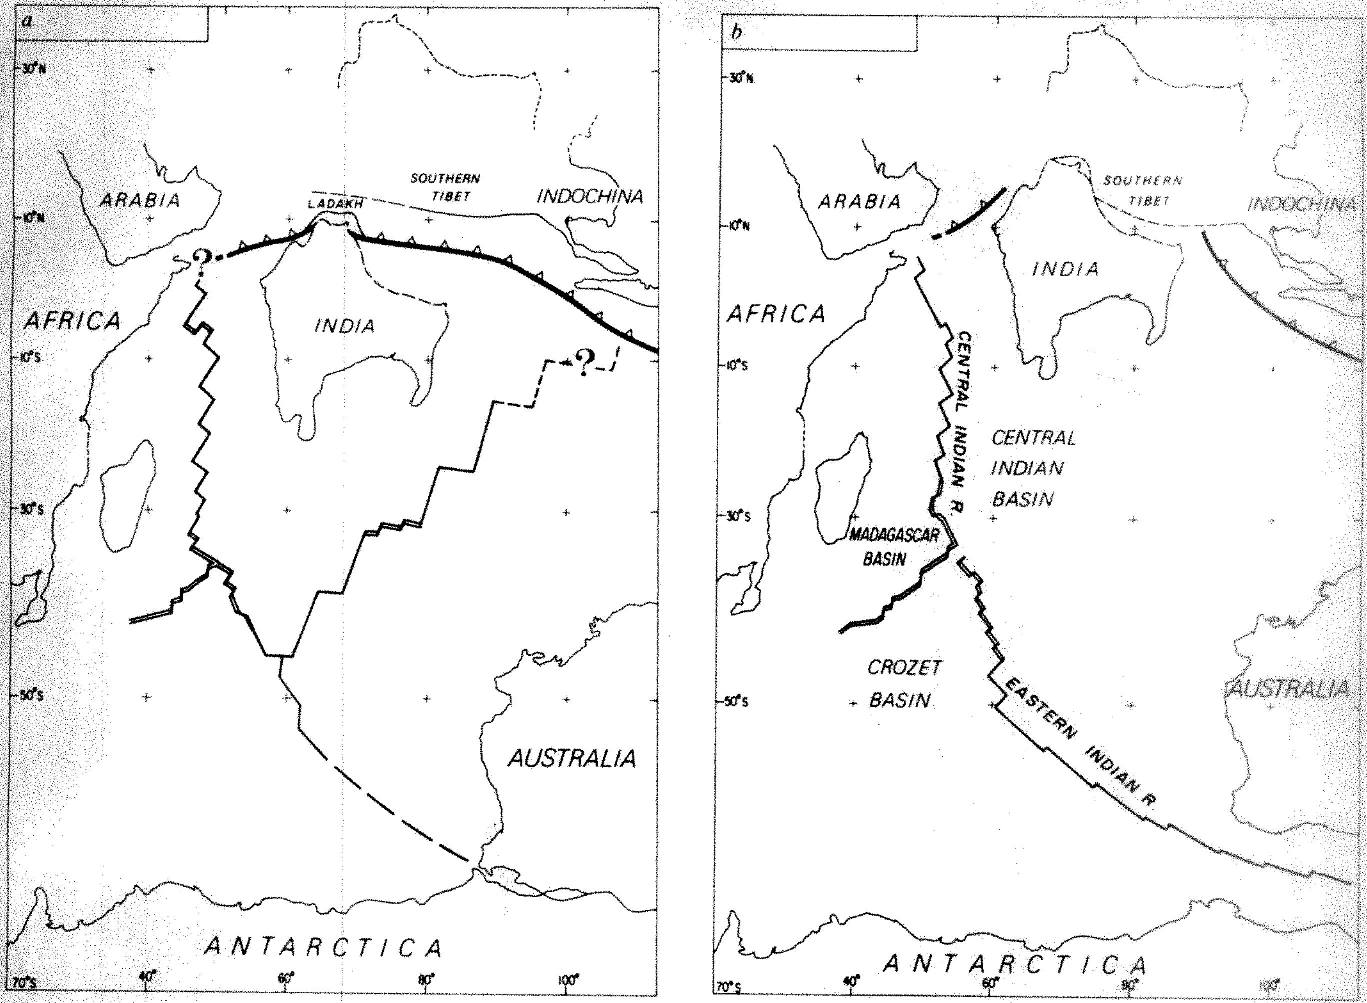

Fig. 4 Plate reconstruction of the Indian Ocean in an absolute frame of reference (hotspot and axial geomagnetic field), before the India–Eurasia collision (at anomaly 24 time, *a*) and immediately after the end of the plate reorganization which followed the collision (at anomaly 18 time, *b*). The contours of Arabia, Africa, Madagascar, Antarctica and Australia were digitized at the 2,500-m isobath. The contours of India were taken at the 500-m isobath (because of the thick series of deltaic sedimentary deposits) and along the Indus–YZSZ to the north (dashed line). The southern margin of Eurasia is reconstructed from palaeomagnetic data (southern Tibet, Ladakh and Indochina–Thailand). The present position of the Indus–YZSZ is also shown for comparison (dashed line). Double lines represent the position of spreading centres reconstructed from identified magnetic anomalies[18,19]. The position of other spreading centres is more speculative and may be subject to revision. The subduction zone (barbed line) is located after the distribution of Upper Mesozoic granites in Tibet and southeastern Asia. Euler poles for the motion of Australia with respect to Antarctica are taken from ref. 51. The overlap in the reconstruction at anomaly 24 between Australia and Antarctica is consistent with the model of propagating rift and continental breakup of Courtillot[50].

21). This study also indicates an approximate 20° clockwise rotation of Indochina with respect to Eurasia since the collision, thus allowing Indochina to be restored to its pre-collision position (Fig. 4*a*). The subduction zone is located along the southern margin of Eurasia as suggested by the occurrence of Upper Mesozoic granites (see ref. 30). Although, as discussed above, ~700 km of crustal shortening is likely to have occurred within the Indian continent, the northern limit of India before the collision is indicated by the Indus–YZSZ in Fig. 4*a*.

The slab-pull force associated with subduction zones is a dominant force controlling the direction of motion of a plate[41,42]. Indeed, the sequence of events associated with the collision and the plate reorganization are all very consistent with this hypothesis. First, as discussed above, the dramatic decrease of the Indian plate velocity at anomaly 22 time (50 Myr) is associated with the closure of the Neotethys in Tibet. This event affected >50% of the total length of subducting boundary of the plate (Fig. 4*a*). However, the northward motion of India continued until anomaly 20 time (44 Myr) when a new regime of plate tectonics was established in which India and Australia became a single plate. This 5-Myr delay between the initial contact (closure of the Neotethys) and this major plate reorganization corresponds, as seen in Fig. 1, to the subduction of 300–500 km of Indian continental crust beneath Tibet. This value is in agreement with earlier estimates of the amount of continental crust which can be subducted in a trench[43] suggesting that the plate reorganization did not occur until subduction had nearly stopped beneath Tibet, when the slab-pull force acting on the Indian plate along the colliding boundary was balanced by the buoyancy of the subducted continental crust. This is further indicated by the convergence rate between India and Eurasia which continues to decrease rapidly until anomaly 20 time and keeps a nearly constant values afterwards (Fig. 2).

As shown in Fig. 4*b*, India and Australia have become part of the same plate after anomaly 20 time. A counterclockwise rotation of India with respect to Eurasia is observed since that time (Fig. 1). This rotation is also indicated by palaeomagnetic studies on DSDP cores in the Indian Ocean[44] and on the Deccan Trapps in India[45] and is matched in southern Tibet by a similar counterclockwise rotation with respect to Eurasia[1]. This is in agreement with the fact that the suturing of India against Eurasia had been completed by anomaly 20 time. The distribution of subducting boundaries bordering the new larger Indian plate, essentially the New Guinea and Java trenches, is consistent with the observed counterclockwise rotation in the late Cenozoic in the hypothesis of a driving mechanism dominated by slab-pull forces. Furthermore, this rotation of the Indian plate is likely to imply the onset of a convergent relative motion at the India–Pacific plate boundary. Indeed, one observes the creation in the early Tertiary of several thousands of kilometres of new subduction zones along the southwestern boundary of the Pacific plate (Tonga–Kermadec, Macquarie; see refs 41, 46). The bend observed in the Hawaian–Emperor seamount chain has been interpreted as evidence for a change in the absolute motion of the Pacific plate and shown to be consistent with the redistribution of slab-pull forces acting on this plate[41].

The bend in the Hawaian–Emperor chain occurred near 42 Myr. Thus, the time lag between the onset of a convergent motion between the two plates (the end of the plate reorganization in the Indian Ocean) and the creation of new slabs acting on the plate (and producing the change in the direction of plate motion evidenced by the bend) is of the order of 2 Myr. McKenzie[47] has shown that the creation of a new trench may be considered as a finite amplitude instability which develops in an elastic plate only for a horizontal convergence greater than 180 km (for a slab dipping at 45°). For a typical relative plate velocity of 10 cm yr^{-1}, the 2-Myr time lag observed corresponds to a horizontal convergence of the order of 200 km.

The observed chronology of events during the plate reorganization also suggests that ridge-push associated with the thermal structure of plates is not a dominant driving force and that seafloor spreading is a passive phenomenon. Indeed, the change in spreading direction of the Indian plate seems to occur in the vicinity of the triple junction before spreading ceased in the eastern Indian basin. The new direction of spreading on the central and eastern Indian ridges tends to be more parallel to the ridge between India and Australia, and thus, the termination of spreading at this ridge seems to be a consequence rather than a cause of the plate reorganization.

Crustal shortening mechanisms

Palaeomagnetic studies in Tibet have shown the existence of 1,900 ± 850 km of shortening within Eurasia since the collision[1]. The present comparison of palaeomagnetic data and reconstructions based on magnetic anomalies document an additional 700 ± 300 km of convergence between India and southern Tibet. Thus, the total north–south shortening resulting from the collision between India and Eurasia amounts to 2,600 ± 900 km.

The last shift observed on India's motion occurred at anomaly 13 time (Fig. 1). This could be regarded as an artefact of our reconstructions since the finite rotations for the closure of the Atlantic Ocean were computed at anomalies 24 and 13 (see ref. 17). However, this shift appears both in the motion of India relative to Eurasia (Fig. 1*a*) and relative to the hotspot frame of reference (Fig. 1*b*). It thus seems to indicate an actual change in the motion of the Indian plate. The motion observed between anomalies 18 and 13 corresponds to several hundred kilometres of left lateral strike-slip motion between India and Eurasia in addition to north–south shortening. Tectonic studies in Tibet have shown the frequent occurrence of a large component of strike-slip motion along thrust faults and suture zones[5] (YZSZ, Bangong–Nujiang suture, Yangbajain thrust, MCT). In addition, palaeomagnetic studies have shown internal deformation to occur in Tibet, in the vicinity of large thrust faults[1,34]. The present observations suggest that strike-slip motion and penetrative deformation may have been contemporaneous with reverse faulting during the early phase of the collision.

After anomaly 13, transverse motion is no longer observed and >1,500 km of shortening still occurred within Eurasia while India moved steadily northward and rotated counterclockwise[1]. This change near anomaly 13 may be interpreted as a change in the mechanism of shortening of Eurasia. The oldest magnetic lineations in the South China Sea have been identified as anomaly 11 (32 Myr)[48]. Following Courtillot[49], we interpret the magnetic quiet zone as the consequence of continental rifting. Initial rifting is thus likely to have begun near anomaly 13 in the South China Sea. Tapponnier *et al.*[3] have related this rifting with the occurrence of left lateral strike-slip motion along the Red River fault which allowed the rotating extrusion of the Indochina block out of the way of the Indian indenter.

Thus, we suggest that the crustal shortening which followed the collision occurred in three episodes. First, from the initial collision to anomaly 20, say from 50 to 44 Myr, shortening occurred mainly by subduction of ~400 km of Indian continental crust beneath southern Tibet. This initial phase terminated when the buoyant resistive force opposed the subduction. Then, from anomaly 20 to anomaly 13 time, between 44 and 37 Myr, shortening continued essentially through crustal thickening by continental underthrusting and internal deformation. During this second phase, left lateral strike-slip motion was also taking place and the total associated north–south shortening is of the order of 300 km. Finally, since that time, shortening within Eurasia has been mostly taken up by block rotation and lateral extrusion along large left-lateral strike-slip faults as proposed by Tapponnier *et al.*[3,4]. This last phase was initiated by activation of the Red River fault and associated rifting in the South China Sea.

Of course, the three mechanisms must have overlapped. In particular, during the last phase, lateral extrusion occurred first along the Red River fault shifting afterwards to the Altyn Tagh fault. During the transition the two other shortening mechanisms must have been active to allow the northward movement of India. In addition, seismic observations indicate that underthrusting is currently observed south of the Himalayas (MBT). However, the present data seem to indicate that during each episode, one particular mechanism dominated. Therefore, if we assume that during the third phase some 80% of the shortening results from lateral extrusion, this mechanism accounts for more than 1,500 km of north–south convergence of India and Eurasia. Because the two other mechanisms account for ~1,100 km of the total shortening, lateral extrusion appears to have been the most efficient in deforming the continent.

Conclusion

The analysis of Cenozoic magnetic anomalies in the Indian Ocean confirms that the collision between India and Eurasia began at anomaly 22 time, that is 50 Myr ago. This age is consistent with all previously available bounds given by geological or geochronological observations. In particular, it is very consistent with the age of volcanics in the Lhasa area. A K–Ar study on an ignimbrite indicates an age of 48.5 ± 1.5 Myr (ref. 33). Also, several $^{39}\text{Ar}/^{40}\text{Ar}$ analyses on andesites show an important grouping of ages at 50 Myr (ref. 50). The collision with the Ladakh island arc probably occurred earlier, near 54 Myr, but it does not seem to have affected the motion of the Indian plate.

A comparison with palaeomagnetic data in southern Tibet (the southern margin of Eurasia before the collision) shows that 'greater' India extended between 500 and 1,000 km further north than the present northern limit of the Indian continent (the YZSZ). The total continental shortening of India and Eurasia produced by the collision is 2,600 ± 900 km and seems to have occurred in three successive phases.

The termination of subduction beneath Tibet at 44 Myr (anomaly 20 time) produced a change in the direction of motion of the Indian plate. This resulted in the termination of spreading between India and Australia which became attached, and a sudden increase in the spreading rate between Australia and Antarctica[18,40]. This plate reorganization in the Indian Ocean preceded the shift in the direction of absolute motion of the Pacific plate evidenced by the bend of the Hawaian-Emperor chain. This shift may therefore be interpreted as a consequence of the India–Eurasia collision. Finally, the relative chronology of this plate reorganization, which is well constrained by the present study, is very consistent with the hypothesis that the slab-pull force associated with subduction zones is a dominant driving mechanism of plate tectonics.

This work has benefited from many discussions with C. Jaupart. This is IPGP contribution no. NS 776.

This article reports new palaeomagnetic results from precisely-dated late Palaeocene limestones from the former northern margin of the Indian subcontinent, now in Tibet, between the major Himalayan thrusts and the India–Tibet suture zone. Convergence in the suture and intracontinental thrusting can be estimated separately and are respectively found to be of the order of 550 km (±650 km) and 400 km (±400 km). Comparison with kinematic models derived from magnetic anomalies constrains the age of the collision at about 50 Myr.

CRUSTAL shortening in major orogenic belts involves, in addition to folding, one or several modes of deformation: subduction of continental crust in the wake of pre-existing oceanic subduction, and sideways escape of crustal blocks along major strike-slip faults (see refs 1–4). A direct measurement of the amount of shortening is often not possible and the relative contributions of each mode have remained highly controversial, particularly in the case of the world's largest orogen, the Himalayan range and associated Tibetan plateau[5–9]. Palaeomagnetism remains the only indirect means of obtaining quantitative estimates.

Continental collision of India with southern Tibet, at that time the southern active margin of Eurasia, occurred in the late Palaeocene–Eocene. The rough original estimate of the age of collision was based on the drastic change in relative motions observed in magnetic anomalies from the Indian Ocean[10]. Large-scale continental shortening followed, firstly, along the original Indus–Zangbo suture zone and then to the south of the suture, along newly developed major continental thrusts such as the Main Central thrust (MCT) and Main Boundary fault (MBF) south of the High Chain, or the recently identified Kangmar thrust (KT) to the north of the High Chain[3,11]. The amount of convergence along the suture remained essentially unknown, and estimates of convergence along the intracontinental thrusts were a cause of great controversy, ranging from 200 km or less[8] to >1,500 km (ref. 6 and see also refs 5, 7, 9). A study of middle Cretaceous red beds and Palaeocene–Eocene volcanics from southern Tibet (Lhasa Block) has recently constrained the total amount of post-80 Myr (and, with some uncertainty on age, post-60–50 Myr) convergence between India and southern Tibet o 1,400±900 km (ref. 4).

Geological setting

During the first (1981) and the third (1983) French–Chinese geoscience expeditions to Tibet, we sampled an outcrop of early Cenozoic shallow marine sediments deposited on the northern margin of India (Fig. 1). The series starts with grey limestones rich in foraminifera (*Nummulites, Orbitolites*) and dated as Thanetian to Illerdian (that is between 50 and 60 Myr, ref. 12). The shallow water depositional environment is clearly demonstrated by algae and polyps. The limestones are conformably overlain by reddish fine-grained sandstones, witnessing the progressive rise of the Indian margin above water level. The entire sequence lies conformably over Cretaceous limestones and shales and appears to be analogous to the Spiti sequences in Ladakh[13]; it is folded in a large synclinorium, trending 110° N and verging south (Fig. 2). The entire unit is located structurally to the north of the MBF, MCT (and High Chain) and to the south of the KT and Zangbo suture (Fig. 1).

Age determination and palaeomagnetic results

Oriented hand samples were taken near Dingri (Figs 1, 2) in limestones (sites XPP 24, 25; XPB 62, 63) and sandstones (site XPB 60). Accurate biostratigraphical age determinations were made by Feinberg, ages and faunas being scaled to the Contessa section in Italy[14]. Deposition of the limestones was found to

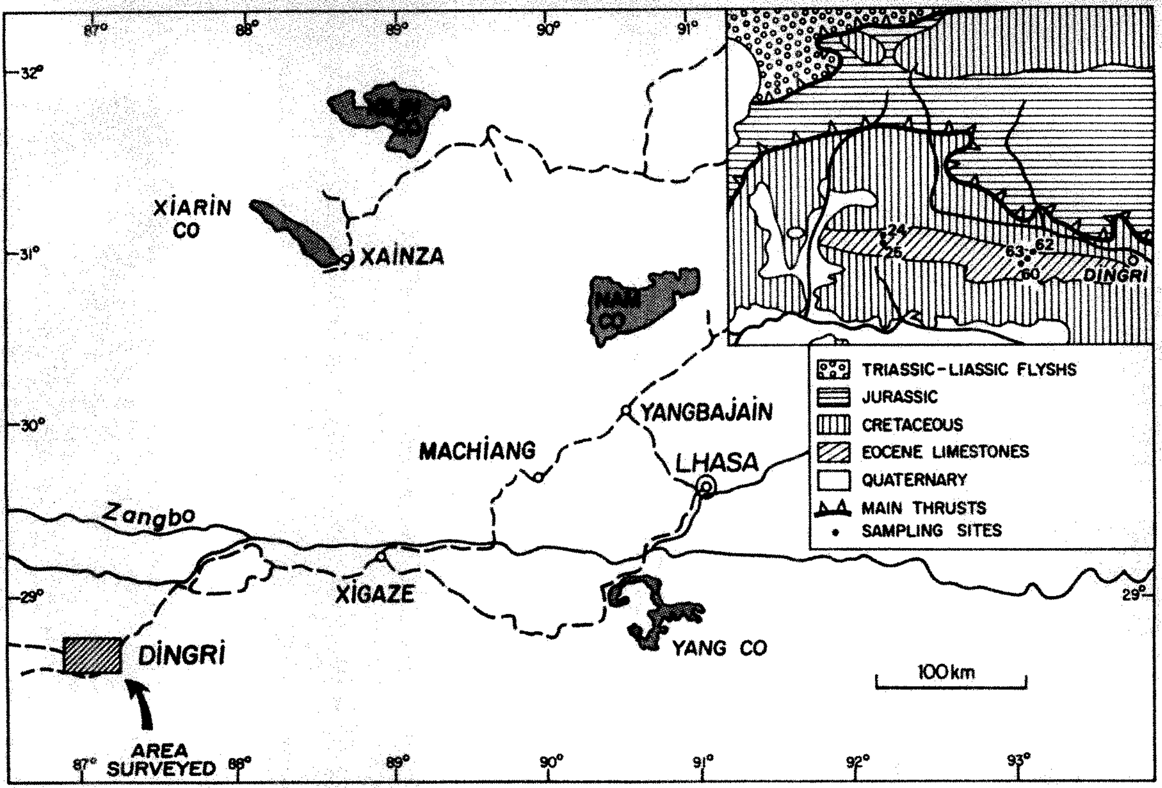

Fig. 1 Geographical map of the sampling area and schematic geological map (inset, after refs 11, 13).

have occurred strictly between anomalies 26 and 25. A comparison of various magnetic polarity time scales[14–16] leads to an age of 57 ± 1 Myr. Specimens were cored from the samples in the laboratory and demagnetized by step-heating followed by cooling in approximately field-free space (20 nT), or by using alternating fields (AF). Magnetic measurements were done with a two-component CTF cryogenic magnetometer. Most samples had weak multicomponent magnetizations which were separated with a modified version of Kirshvink's principal component analysis[17].

Only three limestone sites provided reliable directions. The magnetization of specimens from site 25 fell below 5×10^{-6} A m^{-1} at 200 °C. Typical vector demagnetization plots are given in Fig. 3. Two distinct components (A and B) are clearly indicated for the limestone specimens. Component B disappears after heating at 250–300 °C. The mean direction for sites 24, 62 and 63 is declination, $D = 14°$, inclination $I = 11.5°$ ($\alpha_{95} = 11.5°$) before bedding correction. This is significantly different from either the present geomagnetic direction ($D = 0°$, $I = 43°$) or the dipole direction ($D = 0°$, $I = 48°$) at the sampling sites (lat. 29° N, long. 87° E). Applying the bedding correction increases the scatter of the mean direction. This indicates a secondary (post-folding) remagnetization. Note that the points do not follow a Fisherian distribution: the scatter in declination is approximately twice the scatter in inclination (Fig. 4). Component A has unblocking temperatures between 300 and 500 °C and the demagnetization path points to the origin (Fig. 3). The principal carrier of remanence A is thus probably a (titano-) magnetite. Both normal and reverse polarities are observed and a positive fold test is obtained (Table 1, Fig. 4). The resulting mean direction $D = 337.6°$, $I = -4.5°$ ($\alpha_{95} = 14.6°$) is thus pre-folding and probably of primary origin.

The single sandstone site (no. 60) also showed a multicomponent magnetization, with a more complicated behaviour. A scattered component with high-unblocking temperatures (500–640 °C), probably carried by haematite, is close to the A component of limestones after application of a bedding correction (Table 1: $D = 339°$, $I = -10°$, $\alpha_{95} = 24°$). Beyond 620–640 °C, the progressive build-up of viscous remanent magnetization prevents a close study of the final steps of demagnetization. Depending on the lithology of the samples, two components with medium-unblocking temperatures were observed. One, found

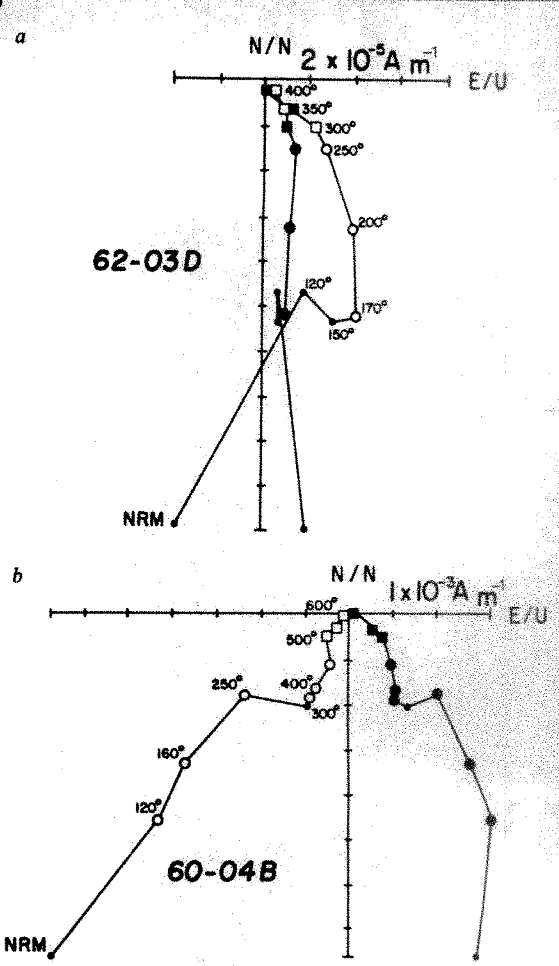

Fig. 3 Typical thermal demagnetization diagrams in geographical coordinates for *a*, a limestone (62-03D) and *b*, a sandstone (60-04B) specimen. Open symbols are for horizontal components, closed symbols are for the component in the north–south vertical plane. Circles are for the lower-temperature B component (remagnetization) and squares for the high-temperature (primary) A component.

between 120 and 450 °C, is close to component B before bedding correction (Table 1: $D = 27°$, $I = 13°$, $\alpha_{95} = 13°$). More interestingly, a second component (C) is found to be $D = 328°$, $I = -2°$ ($\alpha_{95} = 7.5°$) before bedding correction, which is close to component A after bedding correction. The medium-to-high unblocking-temperature components are also revealed by the converging circles method of Hoffman and Day[18] and occur as (alternate) discontinuous linear segments on the vector diagrams, generating a characteristic 'Christmas-tree' pattern (Fig. 3). Both normal and reversed directions are found, often intermediate between directions A and B before and after bedding correction. Secondary components may have an unblocking-temperature spectrum that extends to high temperatures and may be responsible for the scatter of the high-temperature component. These observations (particularly component C), together with the scatter in declination of the B component of limestones, suggest that part of the (re)magnetization was acquired during folding, and part shortly after folding.

The combined high-temperature component A for all sites passes a positive fold test[19] at the 99% level (Table 1). The previous discussion leads us to interpret it as being primary and to assign it the age of 57 ± 1 Myr. The depositional palaeolatitude at that time was then 2.5° S ± 4°, close to and slightly south of the Equator. On the other hand, the B component is a remagnetization, acquired at 6° N ± 5°, during the end or immediately after folding (the age of which is as yet unknown): the fold test is negative at the 99% level. The precise mechanism of overprinting remains unknown although it may be related to the growth of new magnetic minerals, induced by solution transfer under stress.

APWP of India

The determination of continental shortening in the MBT and MCT requires that our data be compared with palaeomagnetic data of similar age from the Indian shield. Such data are unfortunately not available. However, two indirect estimates of the Indian apparent polar wander path (APWP) are available. One determination is based on inclinations from DSDP cores[20], for which, however, no declination control is available. As a result, true palaeolatitudes are systematically underestimated[20]. The lacking declination data are supplemented by magnetic anomaly data. The resulting APWP for India for the period 70–0 Myr (ref. 20) is shown in Fig. 5, together with error circles which are probably underestimates. We redetermined the 60 Myr pole, which is of particular importance here, by discarding highly suspicious results from DSDP sites 215 (basalts) and 217 (sediments).

Because a perfect calibration in age is fundamental here, a new Indian APWP (late Cretaceous and Cenozoic) can be derived on the basis of a detailed study of magnetic anomalies in the Indian Ocean[21] combined with the 'absolute' motion of Africa (with respect to hotspots) deduced by Morgan[22] (see also ref. 23). The new APWP is shown in Fig. 5 and the corresponding palaeomagnetic directions expected for Dingri are listed in Table 2. It is not easy to determine error bars for these estimates. Magnetic anomaly reconstructions contribute an error of the order of 2° (P. Patriat, personal communication, and refs 24, 25), which is not isotropic, and hotspot positions contribute ~2° (as estimated in ref. 25), yielding a total error of about 3°. On the other hand, the age control is excellent[21].

The two APWP estimates are not significantly different after 50 Myr. From 50 to 70 Myr, they are systematically offset (rotated) one with respect to the other, by ~10°. If this difference is significant, it may arise for several reasons, such as systematic

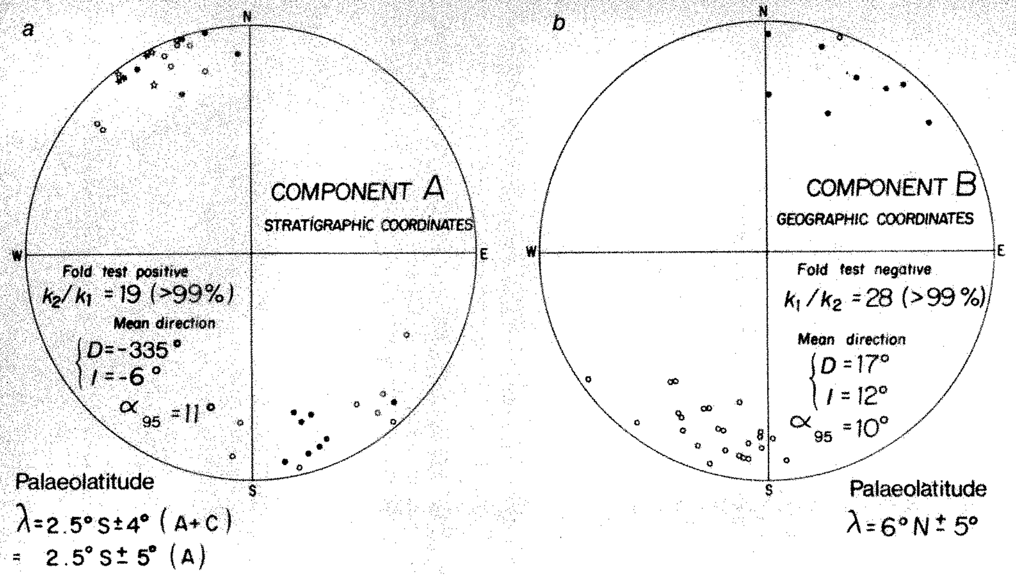

Fig. 4 Stable magnetic directions for all Dingri specimens. A and B (directions in stratigraphical coordinates) are shown as circles, C (in geographical coordinates) as stars (see text and Table 1).

differences between the geocentric axial dipole and hotspot reference frames[25] or more likely from errors in generating the DSDP curve. The only available 70 Myr Deccan trapps palaeomagnetic pole[20] does not resolve this dilemma, as it falls about halfway between the two APWPs (Fig. 5).

Continental convergence and collision

We are now in a position to generate palaeolatitude against time plots for points of the northern margin of India (Fig. 6), namely the former northern edge of continental India, and points now located near Dingri and to the south of it before convergence on the MBF and MCT. Using the data of refs 21, 23, the new APWP for India implies 3.5° ± 4° of convergence south of Dingri (Fig. 6). The DSDP path leads to a larger value of 5.5° ± 4.5°. These values are deduced from the 57-Myr old A component of magnetization. The error estimates are, as usual in palaeomagnetic studies, at the 2σ level and include errors on palaeomagnetic determinations and kinematic reconstructions. Further geological constraints help in reducing them: because we know that convergence definitely occurred between Dingri and India, the latitude difference cannot be negative or even smaller than ~1°, the smallest possible amount of underthrusting in the MBF and MCT.

Using the APWP, one can then generate the latitude history of Dingri as it moved together with stable India before the collision (Fig. 6). When this curve intersects the palaeolatitude for the B remagnetization, the age of this remagnetization is obtained: we interpret this age as the end of folding of the Dingri series, related to blocking of the Zangbo suture due to continental crust subduction. We find this age to be 50 Myr (that of magnetic anomalies 22–23). When error bounds are included for the palaeolatitudes of both magnetizations A and B and the

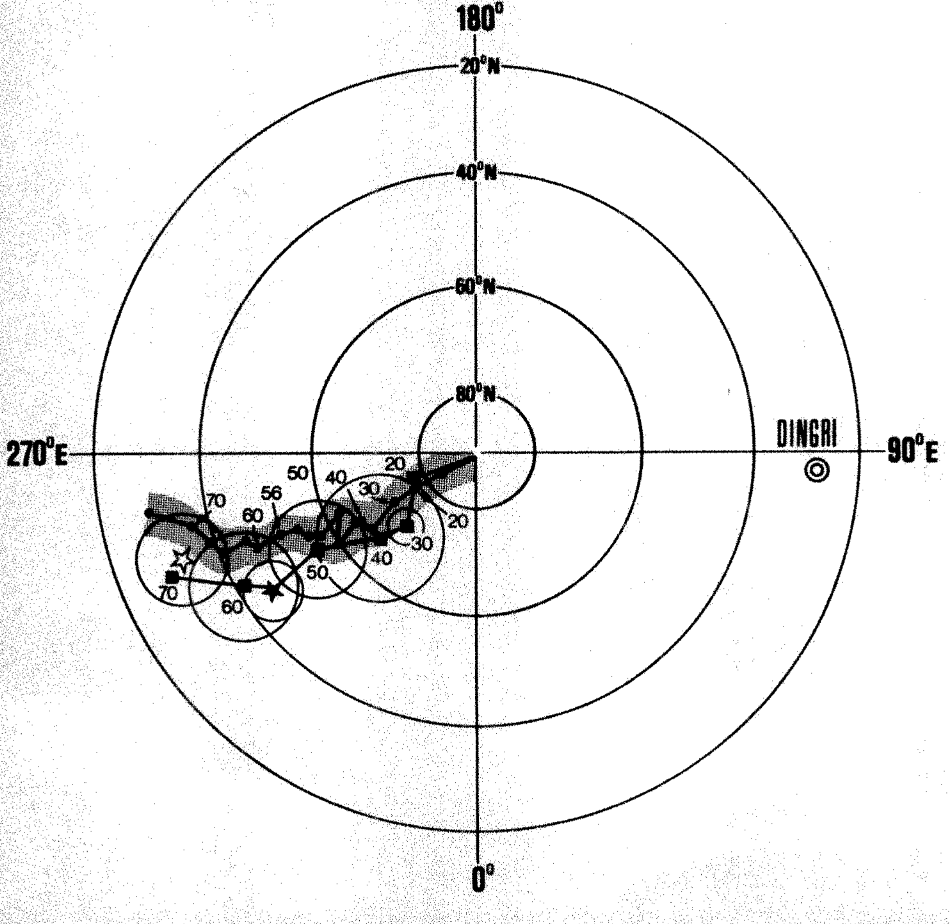

Fig. 5 Two estimates of the APWP for India. ■, From DSDP cores[20]; ●, based on Indian Ocean magnetic anomalies (see refs 21, 23, text, and Table 2); ★, A DSDP pole for 57 Myr, recomputed from ref. 20 (see text); ☆, a 70 Myr Deccan traps pole[20].

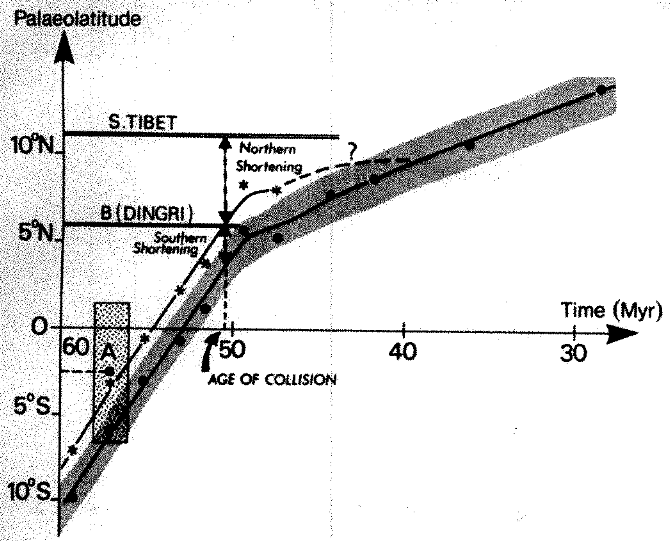

Fig. 6 The northward drift of a point now at Dingri following the motion of cratonic India, as deduced from the data of Fig. 5 and Table 2, is shown as a thick line with error estimates shaded. The primary (A) magnetization for Dingri, also shown with a shaded error box, provides an estimate for crustal shortening in the MBF and MCT to the south. The northward drift of Dingri (thick curve through A parallel to the Indian motion) intersects the B remagnetization, giving the age of the collision and, by comparison with data from southern Tibet[4], the amount of crustal shortening in the Zangbo suture. Error estimates for those are omitted for clarity but are given in the text.

kinematic history of India, this age is found to range between 36 and 59 Myr. However, an age older than 57 Myr (deposition at Dingri) is geologically impossible. An age as young as 36 Myr implies the unlikely combination of (2σ) error bars, with the palaeolatitude of the B component at 10° N and the amount of convergence in the MBF and MCT reduced strictly to zero. The most probable age is unlikely to be older than 53 Myr or younger than 47 Myr (Fig. 6). The age of anomaly 22 happens to be that at which the relative and absolute motions given by Patriat and Achache[23] suddenly slow down and exhibit an erratic azimuthal behaviour which these authors also associate with the collision. Finally, the palaeolatitude of Dingri at 50 Myr can be compared with that of southern Tibet as determined by Achache *et al.*[4], thus yielding an estimate of convergence in the Kangmar thrust and Zangbo suture: 5° ± 6°. The uncertainty on this estimate is still rather large, and further age determinations from the Tibetan (60–40 Myr) volcanics will be helpful. Preliminary results from the ophiolitic complex and flysh series near Xigaze on the Zangbo suture[26] seem to indicate a remagnetization close to 6° N ± 8° which might have been acquired at the same time and under the same circumstances as remagnetization B at Dingri. This might indicate that the 5° estimate of convergence in the Zangbo is on the high side, but further work is needed to refine this analysis. Figure 6 can be complemented by tracing back the motion of the northernmost continental boundary of India before the collision. A schematic series of sections (Fig. 7) also displays the sequence of events before and immediately after the collision. The northern margin of India passed the Equator in the vicinity of Dingri around 56 Myr ago and emergence of Dingri occurred around 55 Myr. The collision (in the sense defined above) occurred around 50 Myr. The deformation history that followed may be deduced from the values presented here and previously published tectonic scenarios[1–4,23]. Approximately 500 km of continental crust (or less) was subducted in the Zangbo before the suture was choked. Part of this may correspond to folding of the Dingri and Xigaze[3,13] series and thrusting (around 40–20 Myr?) on the Kangmar thrust, and the estimate of subducted continental lithosphere might be reduced to a classical value around 300 km (refs 23, 27). When the suture became blocked (around 45 Myr? see refs 1, 2, 23), motion was transferred to the MCT and then MBF, much of the 400 km of convergence determined above occurring by thrusting between 45 and 35 Myr (refs. 28, 29). The amount of folding should, however, be subtracted from these values. Also, thrusting still proceeds to the south of the MBT and elsewhere[9,30]. Propagating extrusion tectonics may have started concurrently to the north of the suture and may account for over two-thirds of the total Cenozoic convergence between India and Asia[1–4].

We thank H. Feinberg for biostratigraphical age determinations and P. Patriat for providing Indian Ocean data. This work was carried out within the Cooperative Research Project of the Chinese Ministry of Geology, Chinese Academy of Sciences, French Centre National de la Recherche Scientifique and Institut National d'Astronomie et de Géophysique. This is IPGP contribution no. 782.

Molecular cloning and expression of cDNAs for the human interleukin-2 receptor

Warren J. Leonard*, Joel M. Depper*, Gerald R. Crabtree†, Stuart Rudikoff‡, Janet Pumphrey‡, Richard J. Robb§, Martin Krönke*, Penny B. Svetlik*, Nancy J. Peffer*, Thomas A. Waldmann* & Warner C. Greene*

§ E.I. du Pont, de Nemours and Co., Glenolden, Philadelphia 19036, USA

We have purified the human T-cell growth factor (interleukin-2) receptor and have cloned, sequenced and expressed cDNAs corresponding to this receptor. We identify one gene, but two interleukin-2 receptor mRNAs which differ in their polyadenylation signals. We have isolated an additional cDNA that may correspond to an alternatively spliced mRNA that lacks a 216 base segment and appears to encode an altered membrane protein which cannot bind interleukin-2.

INTERLEUKIN-2 (IL-2 or T-cell growth factor) is a lymphokine synthesized and secreted by some T cells following activation with antigen or mitogen in the presence of monocyte derived interleukin-1[1]. IL-2 permits long-term growth *in vitro* of T-cell populations serving helper and cytotoxic functions[2-4]. It also augments natural killer cell activity[5], and is being evaluated for possible therapeutic effects in patients with the acquired immunodeficiency syndrome and select neoplasms. IL-2 has been biochemically characterized[6], molecularly cloned[7-9], and is known to be encoded by a single gene[10,11] on human chromosome 4.

In order to exert its biological effects, IL-2 must interact with specific high-affinity membrane receptors[12]. This interaction is critical to the evolution of a normal immune response. IL-2 receptors are not expressed in resting T cells, but they are expressed rapidly following activation with antigen or mitogen. Thus, in contrast to most other hormone–receptor systems, this is an example where both ligand and receptor must be induced. IL-2 receptors are not present in most human leukaemic T-cell lines, but are expressed uniformly in high numbers in human T-cell leukaemia/lymphoma virus-I (HTLV-I)[13,14] infected T cells[15], and it is possible that these receptors may be involved in the uncontrolled growth of these cells.

The IL-2 receptor has been identified as an $M_r = 55,000$ glycoprotein on normal activated peripheral blood T cells[16-18]. These receptors are composed of a peptide precursor of $M_r = 33,000$ (p33). This precursor is cotranslationally modified to a p35/p37 doublet by *N*-linked carbohydrate addition, and then modified in the Golgi apparatus to the $M_r = 55,000$ form. Mature receptors contain *N*-linked and *O*-linked carbohydrate and sialic acid, and are both sulphated and phosphorylated. The receptors on some, but not all HTLV-I infected T-cell lines, vary slightly in mobility on SDS polyacrylamide gels. For example, the receptor on HUT-102B2 cells appears 5,000 daltons smaller than the receptor on normal activated peripheral blood T cells[17,19]. These receptors share the same sized p33 and p35/p37 precursor forms, and the basis for their size difference is the result of altered post-translational modifications, including the amount of sialic acid and sulphate added.

Elucidation of IL-2 receptor structure, function and regulation of expression will improve our understanding of the early events of T-cell activation, including the mechanisms of membrane signal transduction. The availability of cDNA probes to the IL-2 receptor also allows further study of the relationship of these receptors to the adult T-cell leukaemia.

Purification and cloning of receptor

Using anti-Tac, an anti-IL-2 receptor monoclonal antibody[16,19,20], we purified the IL-2 receptor on an immunoaffinity column (Fig. 1). The purified protein, but not control eluates, blocked over 98% of human IL-2 induced proliferation of a mouse cytotoxic T lymphocyte line, suggesting that it indeed possesses IL-2 binding activity (data not shown).

We next determined the N-terminal 29 amino acids of the IL-2 receptor by a combination of sequencing unlabelled purified receptor on a gas phase sequenator and receptor biosynthetically labelled with ^{35}S-methionine, ^{35}S-cysteine, ^{3}H-leucine, ^{3}H-proline, or ^{3}H-aspartic acid on a modified Beckman spinning cup sequenator (Table 1).

An oligonucleotide probe of 17 nucleotides and 64-fold degeneracy homologous to the (−)cDNA strand was synthesized, corresponding to the sequence Cys-Asp-Asp-Asp-Pro-Pro (amino acids three to eight). The 17mer was end-labelled with ^{32}P-ATP and polynucleotide kinase, and hybridized to Northern blots of HUT-102B2 mRNA to confirm that the 17mer identified at least one mRNA species. In fact, we detected two mRNAs approximately 1,500 and 3,500 bases long (data not shown).

A cDNA library (see Fig. 2 legend) was constructed in λgt10 from HUT-102B2 cell mRNA according to the protocol of T. St John, J. Rosen and H. Gershenfeld (unpublished data), except that size-fractionated double-stranded cDNA was purified

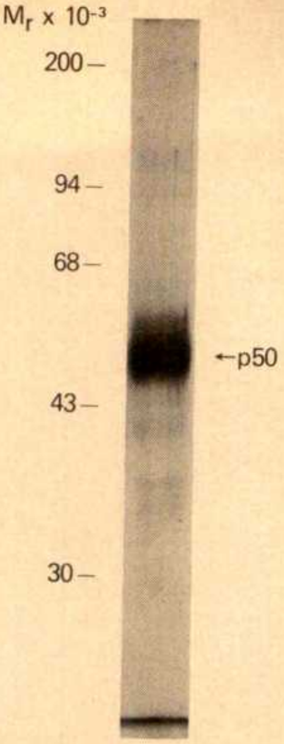

Fig. 1 Purification of IL-2 receptor protein. Anti-Tac and control UPC10 immunoaffinity columns were prepared by coupling purified anti-Tac and UPC10 monoclonal antibodies to cyanogen bromide-activated Sepharose (Pharmacia). Approximately 8×10^{10} HUT-102B2 cells were grown in 10% fetal bovine serum/RPMI medium, collected by ultrafiltration, washed twice in phosphate buffered saline and solubilized in 100 ml extraction buffer (10 mM Tris *p*H 7.4, 0.15 M NaCl, 100 μg ml^{-1} phenylmethylsulphonyl fluoride (PMSF), 0.5% NP40) for 45 min on ice with periodic vortexing. An additional 100 ml of extraction buffer was then added and the cells solubilized for an additional 30 min on ice. Extracts were then centrifuged in a Beckman Ti60 rotor at 37,000 r.p.m. for 30 min at 4 °C. The top lipid layer was discarded and the supernatant collected and stored in aliquots in liquid nitrogen. For each protein preparation, 10 ml aliquots of the extracted cells were passed over a UPC10 column four times, and then over an anti-Tac column three times. The anti-Tac column was washed with 40 ml extraction buffer, 40 ml of 10 mM Tris *p*H 7.5, 0.5 M NaCl, 0.5% NP40, 25 ml of 10 mM Tris *p*H 7.5, 0.1% NP40, and then 10 ml of 10 mM Tris *p*H 7.5. The anti-Tac column was eluted with 3 ml of 2.5% (v/v) acetic acid. The eluted protein was lyophilized, resuspended in 100 μl water and 5 μl analysed on SDS-polyacrylamide gels under reducing conditions: gels were silver stained to assess yield and purity[38]. The columns were then washed extensively and stored in extraction buffer.

Table 1 Sequence of IL-2 receptor

H$_2$N-Glu-$\overset{*}{\text{Leu}}$-$\overset{*}{\textit{Cys}}$-$\overset{*}{\textit{Asp}}$-$\overset{*}{\textit{Asp}}$-$\overset{*}{\textit{Asp}}$-$\overset{*}{\textit{Pro}}$-$\overset{*}{\textit{Pro}}$-Glu-

Tyr-Lys-Glu-Gly-Thr-$\overset{*}{\text{Met}}$-$\overset{*}{\text{Leu}}$-Asn-$\overset{*}{\text{Cys}}$-Glu

Human IL-2 receptor from HUT-102B2 cells (purified using the anti-Tac affinity column) was subjected to automated Edman degradation on a gas phase sequenator and samples analysed by HPLC. Some positions were determined or confirmed by sequencing receptor biosynthetically labelled with ^{3}H-aspartic acid, ^{3}H-leucine or ^{3}H-proline, or with ^{35}S-methionine or ^{35}S-cysteine. For incorporation of radioactive amino acids, cells were grown in the presence of amino acid free RPMI, 5% fetal bovine serum (as a source of unlabelled amino acids) and 1-5 mCi of the radiolabelled amino acid. For aspartic acid, labelling was performed in the presence of 1 mM amino oxyacetic acid, as suggested by Coligan *et al.*[37]. All radioactive amino acids used were the highest specific activity available from Amersham and/or New England Nuclear. *, The positions determined or confirmed by radiolabelled sequencing. The positions italicized represent the amino acids on which the oligonucleotide DNA sequence was based. The 17mer was synthesized and provided to us by Drs Rama M. Belagaje and J. Paul Burnett of Lilly Research Laboratories.

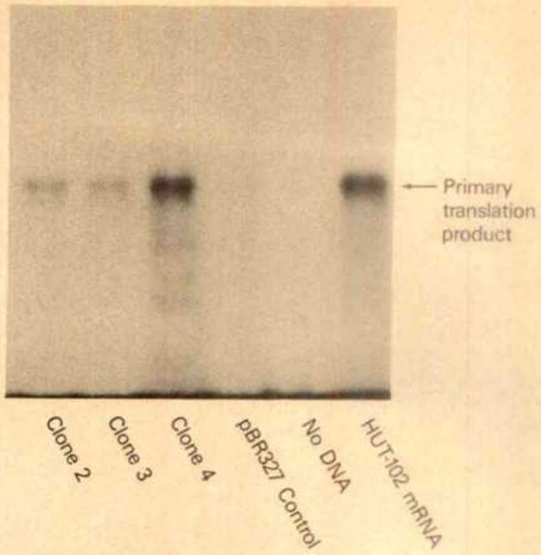

Fig. 2 Preparation of a rabbit heteroantiserum, identification of the primary translation product for the IL-2 receptor, screening of the cDNA library and selective hybridization. Purified IL-2 receptor protein (approximately 3–5 μg) was divided into equal aliquots, one boiled in 1% SDS for 5 min and one not treated, each emulsified with an equal volume of complete Freund's adjuvant, and injected subcutaneously into multiple sites in a New Zealand white female rabbit. The rabbit was boosted (analogous injections in complete Freund's adjuvant) at six weeks. The rabbit was phlebotomized weekly and the ability of the serum to block ^{3}H-anti-Tac binding to activated T cells and to precipitate the IL-2 receptor was assessed. The antiserum specifically precipitated the same 50,000 M_r band from HUT-102B2 cells as did anti-Tac (data not shown) and did not appear to specifically identify any other proteins. Total cellular RNA was isolated from HUT-102B2 cells by the method of Chirgwin *et al.*[39]. The poly(A) fractions were isolated on oligo (dT)-cellulose (Collaborative Research) and translated for 2 h at room temperature in a wheat germ cell-free translation system as described by Gordon *et al.*[40]. The translation mix was then boiled in 2% SDS by the method of Mostov *et al.*[41], cooled to room temperature, diluted to five times the original volume with final concentrations of 1 × phosphate-buffered saline, 1% Triton X100 and 100 μg ml^{-1}PMSF. The mix was cleared with normal rabbit serum and Cowan I strain staphylococcus[42], immunoprecipitated with the heteroantiserum or preimmune serum as previously described and electrophoresed on a gel (sixth lane)[19]. The cDNA library consisted of 2.4 million recombinant phage. 500,000 phage from the library were amplified and approximately 200,000 recombinant phage from the amplified library were screened with the ^{32}P-kinased 17mer. Phage plaques were bound to nitrocellulose as described by Benton and Davis[43], prehybridized overnight at 50 °C in 6 × NET (1 × NET is 0.15 M NaCl, 0.001 M EDTA, 0.015 M Tris, *p*H 7.5), 5 × Denhardts, 0.5% NP40, 200 μg ml^{-1} salmon sperm DNA and then hybridized with the 17mer for 24–48 h in the same buffer containing 10% dextran sulphate. Filters were washed four times for 5 min in 6 × SSC on ice, then for 1 min at 50 °C, and then transferred immediately to 6 × SSC on ice, blotted dry and autoradiographed. Selective hybridization was performed[22] with cDNA inserts from three phage clones subcloned into pBR322: pIL2R2, pIL2R3, and pIL2R4, and with pBR327 and omission of DNA as controls. DNA was linearized by digestion with *Sal*I prior to binding to nitrocellulose, HUT-102B2 mRNA was selectively hybridized, translated, and precipitated with the anti-IL-2 receptor heteroantiserum (first five lanes).

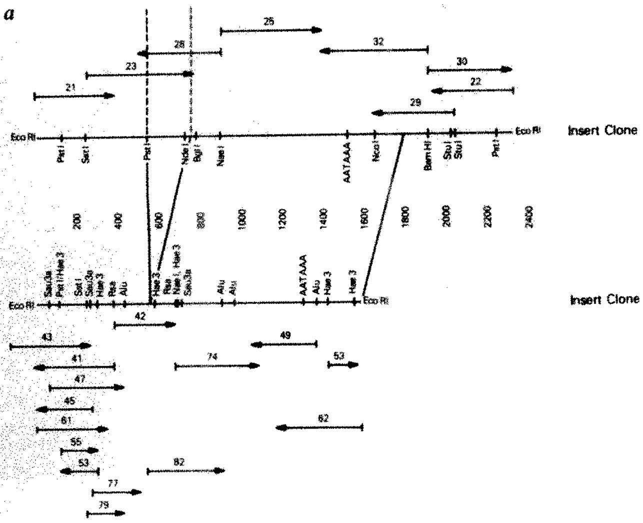
on glass silica mesh[21] rather than by electroelution. In HUT-102B2 cells, IL-2 receptors account for approximately 0.05% of total cellular *de novo* protein synthesis[16].

Eleven clones with inserts of 900–2,300 bases were identified by the 17mer as true positives. Inserts from three of the phage clones were subcloned into the *Eco*RI site of pBR322 (clones denoted pIL2R2, pIL2R3, and pIL2R4, with 900, 2,300, and 1,600 bases, respectively) to facilitate large-scale preparation of inserts. We performed selective hybridization experiments by the method of Maniatis *et al.*[22]. All three recombinant plasmids hybridize mRNA that, when translated in a wheat germ cell-free translation system and immunoprecipitated with a rabbit heteroantiserum to the IL-2 receptor, yield the same sized primary translation product precipitated directly from translations with HUT-102B2 mRNA (Fig. 2). In contrast, control pBR327 and nitrocellulose without DNA added does not selectively hybridize to the IL-2 receptor mRNA. These data confirm that clones 2, 3 and 4 are receptor-associated clones.



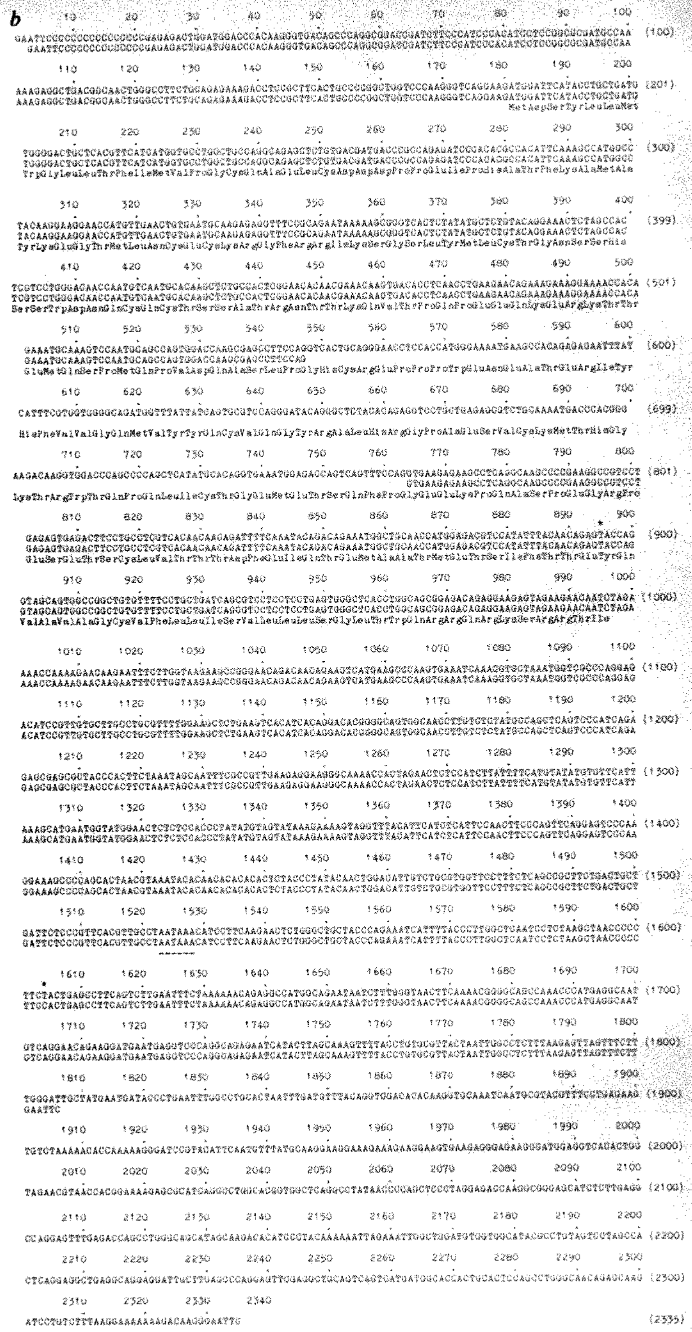


Fig. 3 Restriction map, sequencing strategy, DNA sequence and corresponding protein sequence of IL-2 receptor cDNA. *a*, Restriction map of cDNA inserts of pIL2R3 (clone 3) and pIL2R4 (clone 4). Note the location (vertical dashed lines) of the splicable segment in pIL2R3 that is not present in pIL2R4. Clone 3 was directionally cloned into M13 phage using *Eco*RI, *Sst*I, *Nae*I, *Bam*HI, and *Stu*I restriction sites. Clone 4 was sequenced using four base restriction enzymes *Rsa*I, *Hae*III, *Alu*I, and *Sau*3aI. *b*, DNA and protein sequences for the IL-2 receptor. The DNA sequences of clones 3 (top row) and 4 (second row) are shown with deduced amino acid sequence (third row). The N-terminal amino acid (glutamic acid) and the AATAAA polyadenylation signal which may be used in the 1,500 base mRNA are underlined. The T at 895 (under the asterisk) in one of four sequencing runs was a C. We cannot distinguish with certainty whether position 1,604 (under the asterisk) is a C or a T, which may represent a difference between the two clones.

Sequence of pIL2R3 and pIL2R4 cDNA inserts

The inserts of pIL2R2, pIL2R3 and pIL2R4 were subcloned into M13 bacteriophage and their complete nucleotide sequences by the dideoxy chain termination method[23-25]. The restriction maps and sequencing strategy of pIL2R3 and pIL2R4 inserts (Fig. 3*a*) and the DNA sequences for each (Fig. 3*b*) are shown. We analysed and compared the DNA sequences on an IBM system 370 computer using the program described by Queen and Korn[27] and with the assistance of Dr M. Kanehisa on a Vax computer (Digital Equipment Corporation). Clones 2, 3 and 4 each contain long open reading frames, including the 87 bases corresponding to the 29 amino acids determined by protein sequencing. The N-terminal amino acid of the mature receptor is located at base 244. There are three potential initiator ATGs in the correct reading frame at amino acid positions −21, −15, and −7 (bases 181-183, 199-201, and 223-225, respectively). Preliminary data from sequencing of an ^{35}S-methionine labelled primary translation product suggest that the initiation site is at amino acid −21. All clones had C-tails at the 5′ end added during cDNA synthesis (St John, Rosen and Gershenfeld, unpublished data), but lacked 3′ poly(A) tails. We hypothesize that the poly(A) tails and a part of the 3′ untranslated region may have been lost due to 5′ to 3′ exonuclease activity on the first strand cDNA during second-strand synthesis, since the holoenzyme DNA polyermase I instead of the Klenow fragment is used in the protocol.

Analysis of the sequence of clones 3 and 4 reveals that they differ in two principal ways. First, clone 4 encodes a smaller peptide (179 amino acids; 20,070 daltons) than does clone 3 (251 amino acids; 28,437 daltons). These proteins share the same amino- (base 244) and carboxy- termini (TAG at 997-999 in clone 3) and both contain 2 potential N-linked glycosylation sites (asparagines at bases 388-390 and 445-447), but clone 4 lacks 216 bases (72 amino acids) in the middle of the protein coding region. In clone 3, this region is present and is bounded by the sequence TTCCAGGT on both sides (bases 542-549 and 758-765), and therefore is a segment flanked by a typical messenger RNA donor and acceptor splice site[27,28]. Second, clone 3 extends further 3′ than clone 4, but neither clone reaches a terminal polyadenylation signal sequence (AATAAA).

Expression of IL-2 receptor cDNA

We predict a molecular mass for the IL-2 receptor of 33,000 daltons based on apparent M_r on SDS gels for the putative

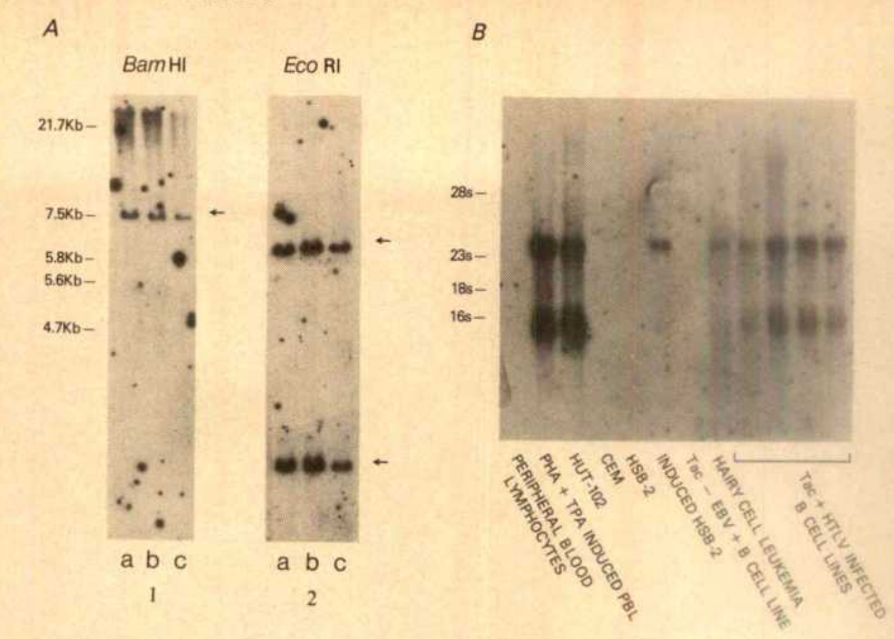

Fig. 4 *A*, The IL-2 receptor appears to be encoded by a single-copy gene. DNA from human placenta (lane *a* of each panel) and tonsils (lanes *b* and *c* of each panel) was digested with *Bam*HI and *Eco*RI, transferred to nitrocellulose, and hybridized with nick-translated pIL2R2. The blotted DNA was provided by Dr Ajay Bakhshi. DNA was digested with *Bam*HI (panel 1) and with *Eco*RI (panel 2). *B*, IL-2 receptor mRNA expression in various lymphoid cell types. 10 μg of poly(A)$^+$ RNA from each indicated cell type was electrophoresed on a formaldehyde gel, transferred to nitrocellulose and hybridized with nick-translated pIL2R3.

peptide precursor. It seems probable that clone 3, which encodes the larger protein product, is the correct one, despite the variability that can exist in migration of different proteins on SDS gels due to variable association with SDS up to the theoretical level of 1.4 g SDS per gram of protein. To test this hypothesis, we expressed each of the cDNAs in COS-1 cells using the expression vector pcEXV-1, which places the cDNA under the control of the Simian virus 40 (SV40) early promoter and SV40 enhancer sequences (Table 2). Cells transfected with control pBR322 do not bind either ^{3}H-IL-2 or ^{3}H-anti-Tac, whereas cells transfected with the insert from pIL2R3 bind both ^{3}H-IL-2 and ^{3}H-anti-Tac. This binding is specific, as it was completely blocked by excess unlabelled IL-2 and anti-Tac. The receptor on these cells has an apparent M_r of 50,000, apparently identical to the receptor on HUT-102B2 cells, and smaller than the receptor on PHA activated T cells (M_r of 55,000). Transfection with pcEXV-1 containing the clone 4 insert, which encodes a smaller protein than clone 3, does not result in the expression of IL-2 receptors (Table 2). As both expression vector constructs were active transcriptionally, these data demonstrate that clone 3 encodes a functional IL-2 receptor and that clone 4 does not.

A single gene encodes IL-2 receptor

We next evaluated the number of genes corresponding to the IL-2 receptor by hybridizing nick-translated ^{32}P-pIL2R2 to genomic DNA digested with *Eco*RI and *Bam*HI. pIL2R2 has an insert corresponding to bases 1–937 and therefore lacks the C-terminal region of the protein and the 3′ untranslated region. We identified two fragments in the *Eco*RI digests, the larger of which is 5,800 bases long with a third faint band of 10,000 bases (Fig. 4*A*). In the *Bam*HI digests, we identified a major 7,500-base fragment and a second less intense more diffuse band of over 25 kilobases (kb). Hybridization with full-length IL-2 receptor cDNA reveals *Eco*RI genomic fragments of 10, 5.8, 2.4 kb and two smaller fragments, and *Bam*HI fragments of 25 and 7.5 kb. These data suggest a single copy gene, but do not exclude a recently duplicated gene.

mRNA expression and HTLV-I infection

Using an IL-2 receptor cDNA, we find that the pattern of expression of IL-2 receptor mRNA parallels the expression of Tac antigen. Resting Tac-negative peripheral blood T cells contain few, if any, IL-2 receptor mRNA copies (Fig. 4*B*, lane 1). However, Tac-positive peripheral blood T cells activated with phytohaemagglutinin (PHA) plus phorbol myristate acetate (PMA) (Fig. 4*B*, lane 2), and HTLV-I-infected HUT-102B2 cells (Fig. 4*B*, lane 3), contain two mRNAs (approximately 1,500 and 3,500 bases), which hybridize to nick-translated IL-2 receptor cDNA. Tac-negative CEM and HSB-2 acute lymphocytic leukaemic T-cell lines do not contain IL-2 receptor mRNA; induction of Tac expression on HSB-2 cells with PMA[29], however, is associated with the appearance of IL-2 receptor

Table 2 Expression of IL-2 receptors in COS-1 cells

	Experiment 1		Experiment 2	
Transfected plasmid	Unlabelled IL-2 added	^{3}H-IL-2 d.p.m. bound	Unlabelled anti-Tac added	^{3}H-anti-Tac d.p.m. bound
pBR322	−	25	−	60
pBR322	+	17	+	150
pcEXV-1-IL2R3	−	562 ± 11	−	28,588 ± 1,548
pcEXV-1-IL2R3	+	62 ± 18	+	261 ± 0
pcEXV-1-IL2R4	−	12 ± 10	−	252 ± 9
pcEXV-1-IL2R4	+	12 ± 3	+	171 ± 39

0.5 μg of clone 3 or 4 insert were ligated to 0.25 μg of *Eco*RI digested and alkaline phosphatase treated pcEXV-1 (provided by Drs J. Miller and R. Germain). The plasmid was transformed into competent cells and recombinant plasmids with the inserts in the correct orientations selected. 5 μg of each recombinant plasmid or of control pBR322 were transfected into COS-1 cells using calcium-phosphate precipitation. The cells were grown overnight, media changed, and then grown for 48 h. The cells were washed, incubated for 90 min at 4 °C with RPMI 1640 medium containing 3% fetal bovine serum and tested for expression of IL-2 receptors. In experiment 1, 45,000 d.p.m. of ^{3}H-IL-2 with or without a 500-fold excess of unlabelled IL-2 were added. In experiment 2, 194,000 d.p.m. of ^{3}H-anti-Tac with or without a 1,000-fold excess of anti-Tac were added. The cells were then washed four times in medium containing fetal bovine serum and dissolved in 1 ml 0.1 M NaOH. The cell-associated radioactivity was then determined. The machine background of 44 d.p.m. has been subtracted from each data point. Data are expressed as mean d.p.m. bound ± standard deviation determined from duplicate plates. For reference, HUT-102B2 cells, which have approximately 300,000 total (high plus low affinity) IL-2 receptors per cell, bound either 1,160 of 6,500 d.p.m. of ^{3}H-IL-2 or 34,500 of 92,100 d.p.m. of ^{3}H-anti-Tac added per 10^6 HUT-102B2 cells.

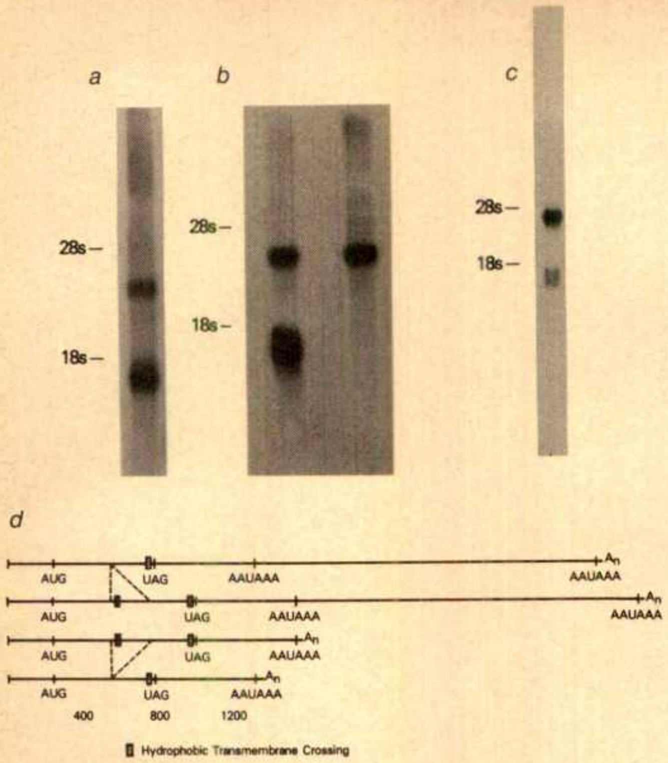

Fig. 5 *a*, Hybridization to HUT-102B2 mRNA with ^{32}P-labelled *Pst*I-*Nde*I segment from pIL2R3. Washes were performed in 0.1 × SSC, 0.1% SDS at 52 °C. *b*, Hybridization to HUT-102B2 mRNA with ^{32}P-labelled pIL2R3 (left lane) or *Nco*I-*Eco*RI 3′ segment of pIL2R3. *c*, Hybridization of ^{32}P-labelled pIL2R3 to mRNA from PHA activated normal T cells. Note that the smaller mRNA appears to be a doublet. *d*, Four possible mRNAs from the IL-2 receptor gene. The top two mRNA (3,300 and 3,500 bases, corresponding to clones 4 and 3, respectively) utilize the same AAUAAA but differ in that the 3,300-base mRNA splices out and the 3,500-base mRNA retains a 216-base segment. The third and fourth are like the second and first, respectively, except that they utilize a more proximal AAUAAA. The third mRNA represents the 1,500-base mRNA retaining the region and the fourth has lost the region and is similar to the 3,300-base mRNA (doublet in *c*).

mRNA. The induced HSB-2 cells express the two mRNAs in significantly different relative quantities. A Tac-negative Epstein-Barr virus (EBV)-transformed B-cell line is negative, but Tac-positive hairy-cell leukaemia cells[30] and Tac-positive HTLV-infected EBV negative B-cell lines (provided by Drs D. Longo and D. Mann) express both IL-2 receptor mRNAs. These data provide a pattern of mRNA expression consistent with our knowledge of which cells react with anti-Tac and express IL-2 receptors, and demonstrate that even in B cells, HTLV-I infection is associated with IL-2 receptor mRNA expression.

We next attempted to determine how the 1,500- and 3,500-base mRNAs differ. A *Pst*I/*Nde*I segment probe from clone 3 (bases 552–729), which contains most of the 216-base pair segment spliced from clone 3 to generate clone 4, hybridizes to both the 1,500- and 3,500-base mRNAs (Fig. 5*a*). These data suggest that both mRNAs contain the segment and that neither corresponds to clone 4. From the sequence and expression data, which together indicate that nonsplicing of the 216-base pair region correlates with IL-2 receptor expression, we hypothesize that both the 1,500- and 3,500-base mRNAs are capable of encoding functional IL-2 receptors. In support of our hypothesis, when mRNA is size-fractionated on a methyl mercuric hydroxide gel, the gel sliced, and RNA contained in the slices translated and immunoprecipitated, the correct primary translation product is identified from either the 1,500- or 3,500-base mRNAs (data not shown).

Both clones 3 and 4 contain two AATAAA sequences corresponding to the potential polyadenylation addition signal present in eukaryotic mRNAs (the first is in the coding region, bases 351–356, and the second is 3′ to the coding region, beginning at base 1,523 in clone 3, and is underlined in Fig. 3*b*). In addition, there is an AATAAA-like sequence (ATTAAA) at bases 1,298–1,303. These AATAAAs apparently are not utilized in clones 3 and 4, as no poly(A) tails are noted and the cDNAs continue 3′ to the AATAAA sites. The functional AATAAAs in clones 3 and 4 are presumably 3′ to the ends of our clones. The *Nco*I-*Eco*RI (Fig. 5*b*) and *Bam*H1-*Eco*R1 3′ fragments of clone 3 (bases 1,642–2,335 and 1,921–2,335, respectively) hybridize only to the 3,500-base mRNA. Thus, we propose that the difference in size of the IL-2 receptor mRNAs is the result of using different polyadenylation signal sequences. In the *Bam*HI-*Eco*RI region, there are two sets of repeated sequences (2,080–2,113 is 82% homologous to 2,213–2,247, and 2,115–2,137 is 87% homologous to 2,279–2,301), although the significance of this finding is unclear. Clone 4 does not arise from either message noted, but its mRNA is identical to that of clone 3 except that the splicable segment has been removed. Such an mRNA (approximately 3,300 bases) would not be resolved from the 3,500-base mRNA corresponding to clone 3 on the Northern blot.

Conclusions

The IL-2 receptor sequence described here has been compared with the Biomedical Research Foundation and Los Alamos databases; no significant homology was found to other known proteins or DNA sequences. Lack of homology to HTLV-I excludes the possibility that this virus encodes the IL-2 receptor. We have shown previously that the primary translation product and other precursor forms of the IL-2 receptor expressed on HUT-102B2 cells are identical in size to those of PHA lymphoblasts, but that there are differences in post-translational processing[17]. Point mutations may thus exist which distinguish these two receptors.

Sequencing of the cDNAs suggests the possibility of alternate mRNA splicing, wherein a 216 base, 72 amino acids long, internal region of the protein may be excised. Whether this region is retained or removed, the encoded protein uses the same initiation and termination sites and shares the identical protein sequence except in the region of splicing. Alternate mRNA splicing has been implicated in the control of gene expression in a variety of different cellular systems. For example, the splicing of alternative exons results in the synthesis of membrane versus secreted forms of immunoglobulin δ and μ genes at different stages in B-lymphocyte maturation[31,32]. Similarly, transcripts from the calcitonin gene are alternatively spliced in neural tissue to produce a calcitonin gene-related peptide which is distinct from the product found in thyroid tissue[33]. Transcripts from the α-amylase and c-*myc* genes in different tissues are differentially processed without altering the protein product[34]. The rat and human γ-fibrinogen genes can be spliced alternatively in the same cell to produce proteins with different functions[35]. Splicing of a segment within the coding region of the IL-2 receptor mRNA appears to change the function of the resultant protein. Transfection of the unspliced cDNA clone in COS-1 cells results in the expression of membrane receptors capable of binding both purified radiolabelled IL-2 and anti-Tac. Transfection of the spliced form of the cDNA, however, does not result in the expression of IL-2 receptors, even though specific mRNA is detected in the transfected cells (data not shown). We assume that this mRNA is translated into protein product that does not bind IL-2, but thus far we have not been able to precipitate the 'spliced' protein product from either surface iodinated or ^{35}S-methionine biosynthetically labelled COS-1 cells. It is also possible that the mRNA is unstable, ineffectively translated, or that the resulting protein product is rapidly degraded. Nevertheless, these data suggest that IL-2 receptor expression may not be regulated solely at the level of transcription, but rather also through post-transcriptional changes in mRNA processing. We cannot exclude the possibility that clone 4 represents a cloning artefact, but the presence of typical mRNA splice signals makes this less likely.

We hypothesize that the four different mRNAs may exist in two pairs, with one of each pair retaining and one lacking the splicable region (Fig. 5*d*). The doublet in the 1,500-base mRNA (Fig. 5*c*) is consistent with the presence of a spliced mRNA, but could also be due to utilization of the ATTAAA sequence.

The DNA sequence of clone 3 permitted us to deduce the entire protein sequence of the human IL-2 receptor. The carboxy-terminus of the protein encoded by these mRNAs contains a stretch of positively charged basic amino acids (6 of the terminal 13 amino acids are arginines or lysines), which we presume to be intracytoplasmic. This region contains one serine and one threonine, which may serve as potential phosphorylation sites[17]. This region is preceded by a hydrophobic region 19 amino acids long which could readily form a transmembrane region (Fig. 5*d*). Both these regions are typical for membrane proteins[36]. There is a second hydrophobic region which is included in the splicable region. Although it is conceivable that this region represents a second transmembrane crossing, the presence of amides (histidine and glutamines) makes this unlikely. If this were a second transmembrane crossing, the two N-linked glycosylation sites would be intracytoplasmic, which is without precedent. It is possible that this region may represent a fold in the protein, a loop into but not through the membrane, or may be important in binding IL-2, which itself has hydrophobic regions. Presumably both of the potential *N*-linked glycosylation sites in the protein are used, as we have identified previously two discrete *N*-linked precursor forms with apparent M_rs of 35,000 and 37,000[16]. In addition, there are numerous serine and threonines immediately extracytoplasmic to the transmembrane region which may serve as the potential *O*-linked glycosylation sites which exist in this protein[16]. The mechanism of signal transduction by this receptor remains unclear, especially in view of the very short cytoplasmic tail (13 amino acids long) which would appear too short to mediate an enzymatic activity. Whether the ligand itself communicates the signal to the cell or whether other proteins serve as subunits in a receptor complex, as has been suggested[16,19], is under further investigation.

Note added in proof: Preliminary S_1 nuclease protection assays suggest that HUT-102B2 cells contain both the spliced and unspliced forms of mRNA indicated in Fig. 5*d*. Since submission of this paper, Wano *et al.*[44] have characterized IL-2 receptors on HUT-102B2 cells and PHA lymphoblasts, with findings similar to those in refs 16–19.

Molecular cloning of cDNA encoding human interleukin-2 receptor

Toshio Nikaido, Akira Shimizu, Norio Ishida, Hisataka Sabe, Keisuke Teshigawara*, Michiyuki Maeda†, Takashi Uchiyama‡, Junji Yodoi* & Tasuku Honjo

Department of Medical Chemistry, *Institute for Immunology, †Chest Disease Research Institute and ‡Department of Internal Medicine, Kyoto University, Faculty of Medicine, Sakyo-ku, Kyoto 606, Japan

The human interleukin-2 (IL-2) receptor was purified by affinity chromatography using the anti-Tac monoclonal antibody, and its N-terminal amino acid sequence was determined. Complementary DNA clones were isolated and sequenced to reveal the primary structure of the IL-2 receptor precursor, which has 272 amino acid residues. The receptor is separated into two domains by a putative 19-residue transmembrane region. Two mRNAs (1.4 and 3.5 kilobases) hybridizing to the cDNA clone were found in human T cells bearing the IL-2 receptor. The cDNA directed synthesis of the IL-2 receptor in COS cells.

THE physiological proliferation of T lymphocytes (T cells) requires a specific interaction between a hormone-like peptide, T-cell growth factor (TCGF)[1] or interleukin-2 (IL-2)[2], and its cell-surface receptor[3-6]. Human IL-2, a peptide of ~14,000 molecular weight (M_r)[7], produced by activated T cells, allows the continuous *in vitro* proliferation of T cells bearing the IL-2 receptor. The immunological activation of G_0-phase T cells, which fail to receive the growth signal by the ligand, requires not only the presence of IL-2 but also expression of the IL-2 receptor. Experiments from several laboratories[8,9] have

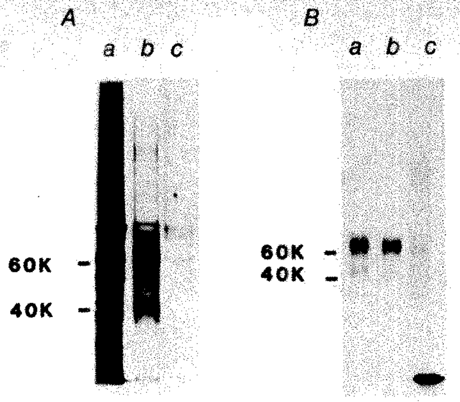

Fig. 1 Purification of the Tac antigen and IL-2 receptor. *A*, SDS-polyacrylamide gel electrophoresis of purified Tac antigen. *a*, Effluent fraction of anti-Tac-Sepharose column (20 μg); *b*, eluted fraction of anti-Tac-Sepharose column (0.1 μg); *c*, buffer alone (to show staining background). *B*, SDS-polyacrylamide gel electrophoresis of the IL-2 receptor of MT-1 cells surface-labelled with ^{125}I-NaI. *a*, Eluate from IL-2-Affigel-10 column (4,250 c.p.m.); *b*, eluate from anti-Tac-Sepharose column (5,200 c.p.m.); *c*, total extracts (4,800 c.p.m.).

Methods: *A*, MT-1 cells (5×10^9 cells) were solubilized with buffer (10 mM Tris-HCl, *p*H 7.4, 0.15 M NaCl, 1% NP40, 1 mM phenyl methyl sulphonyl fluoride (PMSF)). The lysates were absorbed successively with bovine serum albumin-conjugated Sepharose 4B and immunoglobulin (human and mouse)-conjugated Sepharose 4B. The effluent fractions of the solubilized materials were applied to a column (0.5×2 cm) of the anti-Tac antibody coupled with Sepharose 4B (5 mg protein ml^{-1} beads). After extensive washing of the column with PMSF-free solubilizing buffer and a high-salt buffer (10 mM Tris-HCl, *p*H 7.4, 1% NP40, 1 M NaCl), the Tac antigen was eluted with 0.2 M sodium citrate buffer, *p*H 2.6, containing 1% NP40. The eluate was neutralized with 2 M Tris and rechromatographed with an anti-Tac-Sepharose column. An aliquot of the eluted material was precipitated with 10% trichloroacetic acid and run on a 7.5% SDS-polyacrylamide gel[6], analysed with silver stain. *B*, MT-1 cells were labelled with ^{125}I using lactoperoxidase[6]. The solubilized materials were purified by a column of anti-Tac-Sepharose or Affigel-10 conjugated with IL-2 synthesized by recombinant DNA in *Escherichia coli* (1.8 mg IL-2 per ml gel). Eluates from each column and the original extracts were run on a 7.5% SDS-polyacrylamide gel autoradiographed.

Table 1 Expression of Tac-2 cDNA in COS-7 cells

DNA		Antibody	% Positive	MFI
pKCR·Tac-2·A	Expt 1	X5563	1.4	18.8
		Anti-Tac	22.9	56.3
	Expt 2	X5563	1.6	20.2
		Anti-Tac	16.8	46.5
pKCR·Tac-2		X5563	1.4	19.0
		Anti-Tac	7.3	30.4
pKCR·Tac-2·Ai		X5563	3.5	23.4
		Anti-Tac	3.4	24.3
pKCRH2		X5563	1.0	18.5
		Anti-Tac	3.1	24.9

COS-7 cells[46] (500,000) maintained in Dulbecco's minimal essential medium (DMEM) with 5% fetal calf serum (FCS) were seeded onto disposable tissue culture dishes. Medium was washed after 20 h. 4 h later, the cells were supplemented with 1/10th volume of transfection mixtures each containing 40 μg ml^{-1} of the plasmid DNA indicated[47,48]. After 12 h incubation, cells were exposed to 2.5% glycerol in DMEM at room temperature for 1 min, washed and further incubated in DMEM with 8% FCS for 48 h at 37 °C[45]. The cells were collected and stained with anti-Tac monoclonal antibody and fluoresceinated goat anti-mouse antibody (Cappel) as described elsewhere[17]. As paired control experiments, a murine myeloma protein, X5563, replaced anti-Tac antibody. The expression of Tac antigen on the cells were determined by flow cytometry using Spectrum III (Ortho). MFI, mean fluorescence intensity.

demonstrated that antigenic stimulation induces temporal expression of the IL-2 receptor on resting T cells as well as cloned T-cell lines, indicating that the antigen-mediated regulation of the IL-2 receptor expression has an essential role in the clonal expansion of the antigen-specific T cell. As most peripheral as well as thymic T cells do not carry the receptor *in vivo*, the regulatory expression of the IL-2 receptor appears to be a safeguard against a catastrophic spread of the T-cell proliferation by an immunogenic stimulus.

By contrast, an excessive number of IL-2 receptor molecules are expressed on leukaemic cells[10,11] of adult T-cell leukaemia (ATL) endemic in parts of Japan and the Caribbean[12-14]. The leukaemic T cells and the T-cell lines established from these patients contain the DNA sequence of a unique C-type retrovirus, human T-cell leukaemia virus (HTLV)[15] or adult T-cell leukaemia virus (ATLV)[16]. A monoclonal antibody (anti-Tac) produced by using ATL cells as antigens[17], recognizes determinants associated with the IL-2 receptor[18,19]. The number of IL-2 receptors of normal T cells is reduced by interaction with the anti-Tac antibody (down-regulation)[20]. This down-regulation is another abnormal feature of IL-2 receptor expression of ATL cells[11]. This aberrant and excessive expression of the IL-2 receptor might be related to leukaemogenic proliferation of ATL cells[21-23], thus the structure of the IL-2 receptor and regulation of its expression appear to be essential for elucidation of molecular mechanisms of ATL cells. Biochemical analyses of the IL-2 receptor is facilitated by the recent availability of purified IL-2 and monoclonal antibodies recognizing determinants associated with the human and rodent IL-2 receptors[8,9,24-26]. The receptor molecules in these species appear to be similar glycoproteins of about 55,000-60,000 M_r as assessed by mobility in SDS-polyacrylamide gels. Intracellular precursor molecules of the human receptor have smaller molecular sizes, of ~40,000 (refs 5, 6).

IL-2 receptor sequence

We purified the Tac antigen (the putative IL-2 receptor) from an ATL cell line MT-1 (ref. 27) by affinity chromatography with the anti-Tac monoclonal antibody. We find two components of MT-1 of 60,000-65,000 M_r and 40,000-45,000 M_r (Fig. 1*A*). The broad precipitated bands on our gels were essentially the same as those of material internally labelled with ^{35}S-methionine as described previously[5,6]. Pulse-chase experiments have clearly demonstrated that the lower molecular component is a precursor to the surface receptor[5,6]. We also obtained the identical two components by purification with Sepharose conjugated with IL-2 (Fig. 1*B*); we thus confirm here the previous conclusion that the Tac antigen is present on the IL-2 receptor molecule.

The molecular size difference of the two components is thought to be due to different extents of glycosylation; we therefore sought to determine the N-terminal amino acid sequence of the affinity-purified material containing the two components (Fig. 2*A*). We find a unique amino acid sequence from the mixture of the two components, which indicates the identity of the peptide moieties of the two components, although we cannot exclude the possibility that the N-terminus of one of the components is blocked. Short oligonucleotides (14 bases) corresponding to residues 4-8 (Asp-Asp-Asp-Pro-Pro) were synthesized as a probe for screening cDNA libraries.

cDNA clones

A cDNA library complementary to poly(A)$^+$ mRNA of MT-1 cells was constructed and screened with the ^{32}P-labelled 14-base oligonucleotides. The synthetic probes hybridized with three out of 4×10^5 colonies of the MT-1 cDNA library. In the second screening, two of the three candidates hybridized with the probes. After isolation and propagation of the two colonies designated Tac-1 and Tac-2, we cut out the inserts by double digestion with *Hin*dIII and *Pvu*II; both inserts hybridize with the oligonucleotide probes. Restriction site mapping and nucleotide sequence determination show that the two clones are identical, except that the Tac-2 is 16 bases longer at its 5′ end than Tac-1.

The complete nucleotide sequence (1,308 base pairs, bp) of the Tac-2 insert was determined according to the strategy shown

Fig. 2 Nucleotide and amino acid sequences of the IL-2 receptor. *A*, Partial amino acid sequence of human IL-2 receptor. *a*, N-terminal 21 residues of human IL-2 receptor; *b*, possible nucleotide sequences for amino acid residues 4–8, deduced from the protein sequence; *c*, synthesized oligonucleotides complementary to the deduced nucleotide sequence. *B*, Nucleotide and predicted amino acid sequences of the IL-2 receptor. Nucleotides are numbered at right and amino acids are numbered throughout. Residue one corresponds to the N-terminal amino acid residue of the protein sequence. Overline, sites of potential asparagine-linked glycosylation; black bar, underline, poly(A) addition signal; vertical arrow, origin of Tac-1 clone.

Methods: *A*, IL-2 receptor molecules (2 μg, ≈50 pmol) purified by chromatography with the anti-Tac–Sepharose column were analysed with an automatic protein sequencer[35] (Applied Biosystem Inc.). 31 N-terminal amino acid residues were obtained; the first 21 residues were identical (two separate analyses of the same sample). Mixture of 32 possible oligonucleotides (14 bp) complementary to mRNA encoding residues 4–8 were constructed by an automatic DNA synthesizer (Applied Biosystem Inc.). *B*, Restriction fragments isolated with 5% polyacrylamide gel electrophoresis and labelled with [γ-^{32}P]dATP by T4 polynucleotide kinase. Labelled fragments were digested with suitable restriction enzymes, and fragments labelled at one end were isolated with 5% polyacrylamide gel electrophoresis. End-labelled fragments were sequenced according to the method of Maxam and Gilbert[36].

in Fig. 3. The amino acid sequence deduced from the nucleotide sequence contained a stretch matching with the N-terminal 21 amino acid residues of the IL-2 receptor protein (Fig. 2). The complete 272-amino acid sequence reveals several characteristic features of the IL-2 receptor precursor. First, there is a hydrophobic signal peptide of 21 residues common to many secretory or membrane-bound glycoproteins, although the sequence *per se* is unique to each protein.

Second, the IL-2 receptor consists of a 251-residue protein of 28,463 M_r which is slightly smaller than the apparent M_r (40–45 × 10^3) of the intracellular precursor protein purified using the anti-Tac antibody (Fig. 1). The slight difference might be explained if the anti-Tac antibody-immunoreactive precursor protein has already been partly glycosylated at serine or threonine residues (*O*-glycosylation), giving a higher apparent M_r than the primary translation product[5,6]. The high content of serine and threonine residues (19 and 27 residues respectively) and the presence of many clusters of these residues in the protein sequence are consistent with the previous findings that the IL-2 receptor protein is highly *O*-glycosylated. The apparent size difference determined by migration in an SDS-polyacrylamide gel between the precursor and mature membrane protein is mostly due to *O*-glycosylation rather than *N*-glycosylation, as tunicamycin, an inhibitor of the *N*-glycosylation, reduced the size of the mature IL-2 receptor only slightly[6]. There are two possible *N*-glycosylation sites.

Third, the IL-2 receptor molecule has a putative hydrophobic transmembrane domain of 19 residues (residues 220–238). The N-terminal and C-terminal portions may correspond to the extra- and intracytoplasmic domains, respectively, analogous with the epidermal growth factor (EGF) receptor[28]. Another hydrophobic region occurs at residues 118–135. The hydrophobicity of this region is less prominent than that of other transmembrane regions and the amino acid sequence is different.

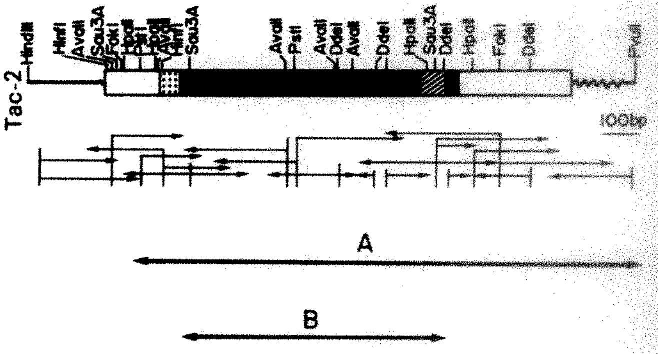

Fig. 3 Restriction cleavage site map of Tac-2 clone and strategy for nucleotide sequence determination. Clone DNAs were cleaved with restriction enzymes and relative locations of cleavage sites were determined. Solid lines, vector; zig-zag lines, oligo-GC (or AT) tails. Black rectangle, coding region; open rectangle, untranslated region; dotted rectangle, signal peptide sequence; hatched rectangle, putative transmembrane region. Direction of mRNA transcription is from left to right. Horizontal arrows show regions and directions of sequencing. Fragment A indicates the insert of pKCR·Tac-2·A (Fig. 5). Fragment B shows probe used for Northern blot hybridization experiments (Fig. 4*A*).

Methods: Cytoplasmic mRNA from MT-1 cells was isolated as described previously[37]. Poly(A)$^+$ mRNA was obtained using oligo(dT)-cellulose. cDNA synthesis and cloning into plasmid were carried out according to Okayama and Berg[38] with a slight modification. Colony screening was performed[39,49] and the probe radiolabelled by phosphorylation using T4 polynucleotide kinase and [γ-^{32}P]ATP to a specific activity of 500 c.p.m. pmol^{-1}.

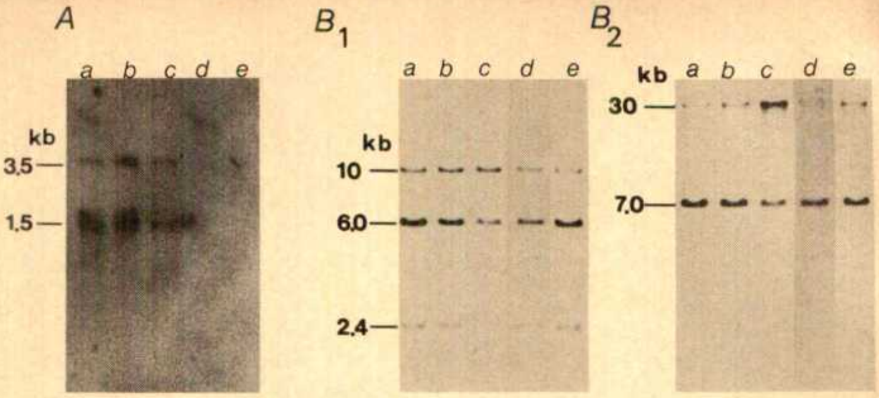

Fig. 4 Analyses of mRNA and DNA of T cells by Tac-2 probe. *A*, Northern blot analysis of IL-2 receptor mRNA. Origins of RNA are: *a*, ATL-2; *b*, MT-1; *c*, YT stimulated with a conditioned medium; *d*, MOLT-4; and *e*, RPMI 8866. MT-1 and ATL-2 were ATLV-positive T-cell lines established from ATL patients. MOLT-4 and YT were ATLV-negative leukaemic cell lines. RPMI 8866 is a human B-cell line. *B*, Southern blot analysis of the IL-2 receptor gene. Origins of DNA are: *a*, Hut-102; *b*, MT-2; *c*, MT-1; *d*, ATL-2; and *e*, human placenta. Restriction enzymes used are: 1, *Eco*RI; 2, *Bam*HI.

Methods: *A*, Poly(A)$^+$ RNAs were prepared from various cell lines[37]. Five μg of poly(A)$^+$ mRNAs were subjected to electrophoresis in a 1.2% agarose gel, which was blotted to a nitrocellulose filter[40]. The filter was hybridized with ^{32}P-labelled fragment B (Fig. 3) of the Tac-2 clone. DNA probe was labelled by nick-translation[41]. *B*, High molecular weight DNAs were prepared from human placenta and established human lymphoid cell lines[42]. DNAs were cut with *Eco*RI or *Bam*HI, electrophoresed in a 0.6% agarose gel and transferred to nitrocellulose filters according to Southern[43]. The filters were hybridized with ^{32}P-labelled *Hin*dIII-*Pvu*II fragment of Tac-2 clone as described elsewhere[44].

mRNA species

Cells stained by the anti-Tac antibody always reversibly bind IL-2, supporting the assumption that the Tac antigen is the IL-2 receptor. This has gained further support by the close correlation between the presence of the Tac-2 mRNA clone sequence and expression of the IL-2 receptor. We assessed the amount of mRNA complementary to the Tac-2 clone in poly(A)$^+$ RNA preparations of various human lymphoid cell lines by the Northern hybridization technique using the 600-bp *Sau*3A fragment (fragment B in Fig. 3) of the Tac-2 clone as probe. Significant amounts of the Tac-2 sequence are present in the ATL cell lines constitutively expressing the IL-2 receptor (ATL-2[30] and MT-1) (Fig. 4*A*). The expression of this gene has been shown in an ATLV-negative human leukaemic cell line YT which had been stimulated to express the IL-2 receptor[29]. As expected, we find little mRNA hybridizing to the Tac-2 insert in non-stimulated YT cells (data not shown).

It is interesting that there are two species (about 1.4 and 3.5 kilobases, kb) of the IL-2 receptor gene transcripts in human T cells. ATL-2 and MT-1 contain an additional mRNA species of 1.6 kb. We show here that the Tac-2 clone, which contains the 1.4-kb insert probably complementary to the 1.4-kb mRNA, is active for expression of the IL-2 receptor in COS cells. We do not know, however, whether the 3.5-kb RNA encodes a functionally active protein. The two mRNAs may encode IL-2 receptors with different affinities for IL-2 (D. A. Cantrell and K. A. Smith, unpublished). The difference could also be accounted for by two alternative poly(A) addition sites as shown in membrane-form immunoglobulin mRNAs[31].

Multiple genomic DNA segments hybridize to the Tac-2 probe (Fig. 4*B*). Human placental DNA contains three *Eco*RI fragments (10, 6 and 2.4 kb) hybridizable to the IL-2 receptor cDNA, and *Bam*HI digestion of human DNA yields two fragments, 30 and 7 kb. The number of bands and relative intensity of each band are the same in ATLV-infected cells and human placenta DNA, suggesting that there is neither amplification nor gross rearrangement of the IL-2 receptor gene in these cell lines (Fig. 4).

The 1.35-kb *Pst*I-*Pvu*II fragment (fragment A in Fig. 3) of the Tac-2 clone has been recloned into an expression vector pKCRH2 (ref. 32). We used the recloned plasmid designated pKCR·Tac-2·A (Fig. 5*a*) to transfect COS cells. After 48 h the cell surface is stained with the anti-Tac monoclonal antibody. Approximately 23% of transfected cells expressed the Tac antigen (Table 1). The pKCR vector and pKCR·Tac-2·Ai containing fragment A in the reverse orientation were used as controls, which are all negative. We also tested the transfected cells for ^{3}H-labelled IL-2 binding (specific activity 25,000 c.p.m. U^{-1}, provided by K. Smith)[3]. COS cells transfected with pKCR·Tac-2·A express on average 2,000 molecules of the IL-2 receptor

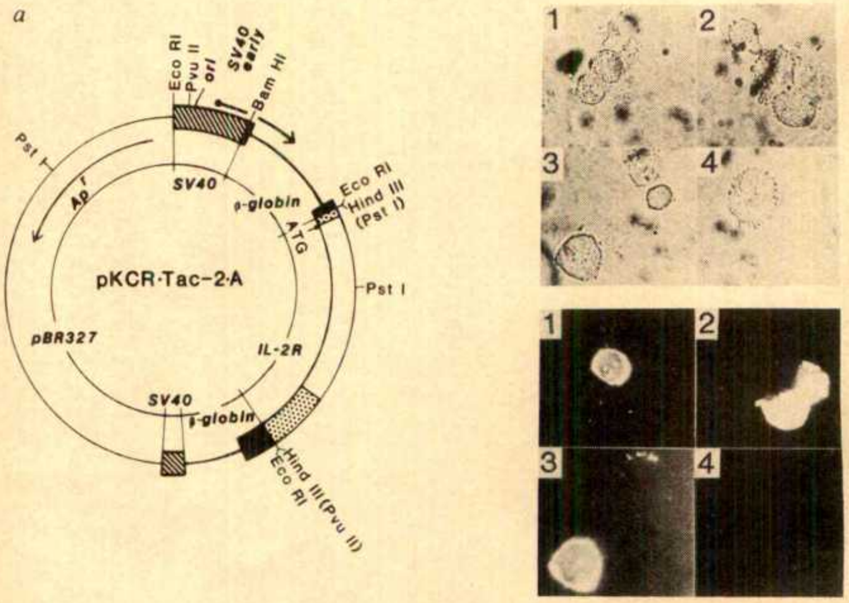

Fig. 5 Structure of expression vector containing Tac-2 cDNA and Tac antigen expression in COS cells. *a*, Structure of pKCR·Tac-2·A. Fragment A of Tac-2 clone (Fig. 3) was isolated by partial *Pst*I cleavage followed by *Pvu*II digestion and ligated with *Hin*dIII linkers after filling single-stranded ends with T4 DNA polymerase. The fragment was cleaved with *Hin*dIII and ligated with pKCRH2 plasmid[32] cleaved with *Hin*dIII (gift of M. Mishina). Recombinant plasmids were cloned and those containing fragment A inserted with the same and reverse orientations relative to the β-globin gene were designated pKCR·Tac-2·A and pKCR·Tac-2·Ai, respectively. A similar recombinant containing the *Hin*dIII-*Pvu*II fragment was also constructed and designated pKCR·Tac-2. Open rectangles, coding sequences; closed rectangles, non-coding sequences of Tac-2; closed boxes, β-globin sequences; hatched rectangles, simian virus 40 sequences; solid line, β-globin gene introns and pBR327; arrow, the origin and direction of transcription; Ori, origin of replication. *b*, *c*, Tac antigen expressed on COS cells. Methods as described in Table 1. DNAs used were pKCR·Tac-2·A (1–3) and pKCRH2 (4). The same fields were observed by phase-contrast (*b*) and fluorescence (*c*) microscopes.

per cell whereas ATL-2 expresses about 8,000 molecules per cell. Our results unequivocally demonstrate that the Tac-2 sequence encodes the IL-2 receptor.

Discussion

The amino acid sequence of the IL-2 receptor does not have any significant homology with any known eukaryotic genes (or oncogenes). Cloning of the IL-2 receptor gene will, however, allow new insights into the physiological function and mechanism by which the IL-2 and its receptor system regulates T-cell proliferation. These include elucidation of the three-dimensional structures of the ligand and receptor which can be produced in large quantities in *E. coli* or mammalian cells, and the molecular mechanisms of signal transmission via surface receptor in the hormone and lymphokine systems, via mutants of the IL-2 receptor gene.

Cloning of the IL-2 receptor gene will also allow us to test several hypotheses proposed for the mechanism of leukaemogenesis of ATL triggered by ATLV, which has no typical oncogene sequence[33]. The excessive numbers of IL-2 receptor on ATL cells may be similar to aberrant expression of the EGF receptor on certain transformed cell lines such as A431 (ref. 34). The homology between the *erb-B* oncogene and the cytoplasmic domain of the EGF receptor[28] has strengthened the hypothesis[21-23] that an excessive amount of the IL-2 receptor might alter the normal growth control of T cells. This can be directly tested by transfection of human T-cell lines by the IL-2 receptor cDNA clone. We can also examine whether the IL-2 receptor gene in ATL cells has any mutations. A unique lymphokine secreted from ATL cells, ATL-derived factor (ADF), enhances the expression of the IL-2 receptor[30]. ADF may be responsible for the continued expression of the IL-2 receptor in many ATLV-positive T-cell lines. It is of interest to know whether ADF is able to induce transcription of the IL-2 receptor gene in human T cells.

We thank Japan Scientific Instrument Co. (JSIC) and Dr I. Kubota (Suntory Ltd) for amino acid sequence determination, JSIC for oligonucleotide synthesis, Dr K. Kato (Takeda Chemical Co.) for supply of IL-2 and Affi gel-conjugated IL-2, Dr T. Miyata for computer analysis of the sequence, and Dr M. Okada, Mr Y. Tagaya and Dr T. Noma for technical assistance. This investigation was supported by grants for special promotion of science from Ministry of Education, Science and Culture of Japan.

Terrestrial catastrophism—Nemesis or Galaxy?

S. V. M. Clube

The ~30 Myr periodicity associated with the Sun's motion through the central plane has been linked to geomagnetic reversals[1,2], biological extinctions[3] and crater ages[4–6]. This periodicity is consistent with galactic theories of terrestrial catastrophism[1,5]. It has been suggested, however, that the periodicity is controlled by a hypothetical stellar companion of the Sun ('Nemesis') in a highly eccentric orbit of arbitrarily chosen period which periodically upsets the Oort cloud[7,8]. Although the idea appears superficially attractive, there has been little or no attempt to relate it to what is already known about the Oort cloud and the environment in which the Sun–Nemesis system would have to exist. Thus, the inferred phase of the Nemesis cycle is inconsistent with such evidence as there may be for a recent disturbance (~5 Myr) of the Oort cloud, namely the apparent non-equilibrium distributions of perihelia[1] and 1/*a* (ref. 9) and the enhancement of the short-period comet population[10,11] (compare ref. 12). It also discounts the generally high glacial, magnetic and orogenic activity on Earth within this period and the Sun's recent passage through Gould's belt[10,13]. However, the most serious problem is reconciling the approximately constant time-averaged cratering rate for the last ~3,000 Myr (ref. 14) and the stability of the proposed system.

The long-period comet system is dynamically unstable, over the lifetime of the Solar System, against the perturbing action of molecular clouds[15–17]. Since the proposed companion star has an aphelion distance $Q \simeq 180{,}000$ AU (that is, $P \simeq 30$ Myr) as against ~40,000–50,000 AU for long-period comets, one expects its orbit to be unstable *a fortiori*. On the impulse approximation the specific energy change ΔE of the companion resulting from a change Δv in its velocity v relative to the Sun is

$$\Delta E = \tfrac{1}{2}(v + \Delta v)^2 - \tfrac{1}{2}v^2$$

or

$$\Delta E = v.\Delta v + \tfrac{1}{2}(\Delta v)^2 \qquad (1)$$

Considering only the random component $v.\Delta v$, Oort[18] derived an expression for the specific energy fed into a body of separation Q from the Sun in $t \times 10^9$ yr, as a result of encounters with

Table 1 Energy injected by various perturbers

Perturber	Energy, Δv^2 $[(\text{cm s}^{-1})^2]$
GMCs with $M = 2\times10^5\,M_\odot$, $\nu = 40\,\text{kpc}^{-3}$	3.8×10^9
Molecular clouds with $M = 2\times10^4\,M_\odot$, $\nu = 400\,\text{kpc}^{-3}$	9.6×10^9
Stars	4.2×10^9
Σ	17.6×10^9
Energy required for escape	0.9×10^8

point masses. Modifying[15] to allow for the effect of penetrating encounters with molecular clouds of mass M solar masses, radii R AU and number density ν kpc^{-3}, one finds

$$\sum \Delta v^2 = 740\nu\left(\frac{M}{2.21\times10^5 M_\odot}\right)^2 \times\left(\frac{Q}{R}\right)^2\left(\frac{t}{4.5\times10^9\,\text{yr}}\right)10^8 \qquad (\text{cms}^{-1})^2 \tag{2}$$

The energy injected by various perturbers over 4.5×10^9 yr is listed in Table 1. According to Sanders[19] recent determinations of the mass of the molecular cloud system agree to within a factor ~2, whilst the column density of molecular clouds is $\sim5M_\odot\,\text{pc}^{-2}$ at the solar distance, the mass-averaged mean mass of giant molecular clouds (GMCs) being $\sim5\times10^5\,M_\odot$. The first two entries in Table 1 each correspond to a column density $\simeq1\,M_\odot\,\text{pc}^{-2}$ and are therefore below the extreme lower limit of mass allowed by the data. There is also considerable substructure within GMCs, which adds substantially to the energy injected: thus GMCs ($\sim10^5$–$10^6\,M_\odot$) appear to comprise aggregates of molecular clouds ($\sim10^4\,M_\odot$). We consider here three extreme models which are likely to encompass all reasonable possibilities: GMCs are uniform throughout their interiors (rows 1+3); GMCs do not exist, only molecular clouds (rows 2+3); GMCs comprise molecular clouds as substructure (rows 1+2+3). It seems that even with the most conservative assumption the energy injected into the Sun/Nemesis binary by molecular clouds and stars is at least an order of magnitude greater than its binding energy and that the system could not survive in its postulated state for 4.5×10^9 yr. Most probably, the sum of the injected energies is ~200 times that required to eject the companion star from the Solar System. The probable survival time can be found from equation (1) by equating the energy input to the binding energy whence it is found that, in the most likely case of rows 1+2+3, the formal survival time is ~50 Myr. Considering only the effect of uniform GMCs (rows 1+3), the survival time is found to be ~100 Myr. The rate of energy input is decreased by a factor ~1.5–2 allowing for the exponential z-distribution of molecular clouds[16], and increased by factors ~2 and ≥2 allowing for gravitational focussing and a more gaseous past Galaxy respectively[17].

The dissolution time τ of a binary system has been derived also by Chandrasekhar[20] neglecting the random component in (1) and considering only the systematic unbinding term $\frac{1}{2}(\Delta v)^2$. Adjusting his formula slightly to allow for the high eccentricity of Nemesis, one finds

$$\tau \simeq \frac{7\times10^{13}}{\nu M Q^{3/2}}\times10^9\,\text{yr} \tag{3}$$

yielding similar survival times, for example $\tau\sim100$ Myr for uniform GMCs with $\nu\simeq40\,\text{kpc}^{-3}$ and $M = 2\times10^5\,M_\odot$. Putting these two effects together (equation (1)), it is evidently unlikely that the Sun–Nemesis system will survive the Galactic environment for more than two or three revolutions.

In addition to the disruptive influence of encounters with molecular clouds and stars, the somewhat lesser effect of the Galaxy's smoothed-out mass distribution has to be considered. The disturbing potential due to the Galaxy is $\phi = -\frac{1}{2}(\alpha x^2 + \gamma z^2)$, with $\alpha\sim1.6\times10^{-30}\,\text{s}^{-2}$, $\gamma\sim-4.8\times10^{-30}\,\text{s}^{-2}$, in a heliocentric rotating coordinate system with x-axis directed towards the galactic anticentre, y-axis in the direction of rotation and z-axis towards the north galactic pole[21]. The critical Hill surface, beyond which orbits around the Sun are unstable, is roughly a tri-axial ellipsoid with $x_{\text{max}}\simeq300{,}000$ AU, $y_{\text{max}}\simeq200{,}000$ AU, $z_{\text{max}}\simeq150{,}000$ AU. Thus with aphelion ~180,000 AU, the orbit of Nemesis is barely if at all stable. Take the orbit to be roughly rectilinear, let χ represent the angle between orbit and x-axis, and consider the perturbing forces acting on the companion while its radius vector $r > a \simeq 10^5$ AU, which will hold for about half the orbital period. Over this time, the x-component of the galactic field satisfies $\ddot{x} = \partial\phi/\partial x \geqslant \alpha a\cos\chi$, whence $|\dot{x}| \geqslant (\alpha a\cos\chi)T/2$. With $a\simeq1.5\times10^{18}$ cm, $T\simeq9\times10^{14}$ s, $\cos\chi\simeq\frac{1}{2}$ one obtains $|\dot{x}|\gtrsim0.05\,\text{km s}^{-1}$. Likewise $|\dot{z}|\geqslant0.15\,\text{km s}^{-1}$. These perturbations should be compared with the aphelion velocity of Nemesis, $\sim0.03\,\text{km s}^{-1}$, and the circular velocity at 180,000 AU, $\sim0.07\,\text{km s}^{-1}$. It is clear that the velocity vector of the companion star will be grossly perturbed around its aphelion: the binary system would not in general maintain the high eccentricity necessary for Oort cloud perturbations and indeed might not survive even a single revolution. Thus, the Galaxy's smoothed-out mass distribution is also an important factor, though if one were to (1) overlook molecular cloud perturbations; and (2) adopt a binary configuration with major axis close to the galactic plane, it is possible such a system might survive for $\geqslant1\times10^9$ yr. Note also that the proposed binary characteristics are very rare or absent amongst observed systems. Thus among binaries with solar type primaries, only ~1% have periods in excess of 0.3 Myr, the computed periods amongst common proper motion pairs ranging from 3.5 to 820,000 yr with mean 67,000 yr and median 3,100 yr. Furthermore, only ~3% of binaries have eccentricities ≥0.75. These facts are of course consistent with disruption by molecular clouds and the Galaxy.

Dynamical constraints on the mass and perihelion distance of Nemesis and the stability of its orbit

J. G. Hills

T-6, Theoretical Division, Los Alamos National Laboratory,
Los Alamos, New Mexico 87545, USA

It has been suggested[1,2] that the observed periodic extinction of species at intervals of 26 Myr (ref. 3) may be catalysed by a hypothetical stellar companion of the Sun, Nemesis, with an orbital period of 26 Myr. The passage of a stellar companion through the inner comet cloud[4] will fill the loss cone of these comets and cause a comet shower to enter the planetary system. It has been estimated that about 20–30 comets will hit the Earth during a shower, which

lasts less than a million yr. Such Earth impacts would produce considerable environmental stress and may lead to widespread extinction of species[4]. I now investigate the effect of Nemesis on the comets in the inner comet cloud. This is used to determine the minimum required mass of Nemesis and its minimum required perihelion distance. The effect of passing stars on the stability of the orbit of Nemesis is investigated, and the probability of its having passed within the planetary system estimated.

My previous calculations[4] were for a passing star in a hyperbolic orbit with an impact velocity of 30 km s^{-1}, which is very much greater than the orbital velocity of a long-period comet. This allowed an impulse approximation to be used. However, Nemesis has an orbit similar to that of the comets in the outer, steady-state or Oört comet cloud, so its orbital velocity is similar to that of the comets which it perturbs. A series of exact three-body calculations are used to determine the amount by which Nemesis perturbs the orbits of the comets in the inner cloud.

I consider comets having semimajor axes of 4,000 AU, which is about the maximum semimajor axis of the comets needed to produce a death shower. In the computer calculations, Nemesis is assumed to be a black dwarf with a mass of either $M_N = 0.05\ M_\odot$, or $M_N = 0.005\ M_\odot$. If the orbital period of Nemesis is 26 Myr and its mass is 0.05 $M_\odot$, the semimajor axis of its orbit is $a_N = 89{,}200$ AU by Kepler's Third Law.

Because of the large semimajor axis of its orbit, Nemesis crosses the orbits of comets having semimajor axes of 4,000 AU at very nearly the parabolic speed. This means that the pericentre passage of Nemesis can be well approximated by modelling it as an object in a hyperbolic orbit with a velocity at infinity of 0.1 km s^{-1}, which is an order of magnitude less than its orbital velocity at pericentre passage. This approximation allowed me to use my massive, very accurate computer code which was originally applied to encounters between a binary system and a stellar intruder (refs 5, 6 and refs therein). The calculations used a representative comet orbit with a semimajor axis $a_c = 4{,}000$ AU and an eccentricity $e_0 = 0.999$ (see Table 1).

The loss cone comets are long-period comets which pass within the orbits of Jupiter and Saturn at perihelion. Such comets are lost by their ejection into hyperbolic orbits in a time comparable with the original orbital period of these long-period comets[5,6]. They are not present unless perturbations by passing stars have deflected fresh comets into the loss cone within the previous orbital period. The latter situation occurs in the steady-state for comets in the classical Oört cloud[4] (comets with semimajor axis, $a_c > 2\times10^4$ AU). Comets with semimajor axis $< 2\times10^4$ AU only have their loss cones filled episodically by passing stars. An intense comet shower enters the planetary system whenever a close stellar passage occurs[4].

To fill the loss cone of the comets in the inner cloud requires that the mean change in their pericentre distance $\langle\Delta q\rangle$ exceed the semimajor axis of the orbit of Saturn or $\langle\Delta q\rangle > 9.5$ AU. Table 1 shows that for a Nemesis mass of $M_N = 0.05\ M_\odot$ and for comets with semimajor axes $a_0 = 4{,}000$ AU, this requires that the closest approach of Nemesis, its pericentre distance, be $<2.6\ a_0 = 1.04\times10^4$ AU. Since the semimajor axis of Nemesis is $a_N = 89{,}200$ AU, this requires that its orbital eccentricity be at least $e_N \geq (1 - R_{min}/a_N) = 0.88$.

The orbit of Nemesis has been greatly perturbed by passing stars, so the probability of its having a given eccentricity is dictated by conditions of statistical equilibrium rather than by its initial eccentricity. The probability of its having an eccentricity e or greater at some arbitrary time is given by[4]

$$P_e = (1 - e^2) \tag{1}$$

For $e = 0.88$, we note that $P_e = 0.23$. Invoking the Ergodic Hypothesis that a time average for one object produces the same distribution as an ensemble average over many objects, we anticipate that ~23% of the time its orbital eccentricity is high enough for Nemesis to induce an intense comet shower at its pericentre passage. For a fixed value of Nemesis's pericentre distance q_N, the mean change in the pericentre distance of the comets with $a_c = 4{,}000$ AU scales as

$$|\Delta q_c| \propto \frac{M_N^2}{M_\odot + M_N} \tag{2}$$

in the impulse approximation. In this approximation, we expect that a Nemesis with $M_N = 0.005\ M_\odot$ would produce a $|\Delta q_c|$ about 96 times smaller than a Nemesis with $M_N = 0.05\ M_\odot$. The scatter in the exact numerical results of Table 1 are fairly large, but they indicate that the lower-mass Nemesis produces a $|\Delta q_N|$ about twice that prediced by scaling from $M_N = 0.05\ M_\odot$ using the impulse approximation.

Applying the scaling law given by equation (2) to the data in Table 1, we can find $|\Delta q_c|$ for other possible masses of Nemesis. Table 2 shows, as a function of M_N, the maximum value of q_N that would still allow the perturbations by Nemesis to fill the loss cones at pericentre passage (that is, still result in $|\Delta q| \geq 9.5$ AU).

If we correct for the small breakdown in the scaling law indicated by the computer calculations for $M_N = 0.005\ M_\odot$, we see that a Nemesis with a mass $M_N = 0.01\ M_\odot = 10$ Jupiter masses may be close to the minimum required mass, but a Nemesis with $M_N = 0.005\ M_\odot$ is well below the minimum mass.

When the loss cone is filled, the fraction of the comets of semimajor axis a_c which have pericentre distances of q_c or less is $F_l = 2q_c/a_c$, for $q_c \ll a_c$ (ref. 4). Here F_l is also the fraction of the comets of semimajor axis a_c which are lost per orbital period due to the perturbations by Jupiter and Saturn if $q_c \leq 9.5$ AU. The fraction of the comets of a given semimajor axis surviving N loss cone fillings is given by

$$F_N = [1 - (2q/a_c)]^N \tag{3}$$

If the loss cone of the inner cloud comets were filled at every perihelion passage of Nemesis for the past 4.6×10^9 yr then $N = N_0 = 177$ assuming the orbital period of Nemesis has remained constant at 2.6×10^7 yr. For comets with $a_c = 4{,}000$ AU and $q_c \leq 9.5$ AU, $F_N = 0.43$ for $N = 177$. In this case, more than half these comets would be lost. However, the orbit of Nemesis is severely perturbed by passing stars. The factor P_e in Table 2 is the fraction of the time that its orbit is eccentric enough and

Table 1 Relaxation of comet orbits by Nemesis

p/a_0	R_{min}/a_0	$\Delta q/(\text{AU})$	N
$M_N = 0.05\ M_\odot$			
2.5	0.134	84.8	100
5.0	0.531	134	551
9.0	1.68	149	551
10.0	2.06	79	551

12	2.91	4.1	100
15	4.41	1.7	100
20	7.41	0.7	100
$M_N = 0.005\ M_\odot$			
5.0	0.554	2 3	551
9.0	1.75	7.4	551
10.0	2.14	1.3	551
11.0	2.57	0.54	551

$V = 0.1$ km s^{-1}; $a_0 = 4\times10^3$ AU; $e_0 = 0.999$. Impact parameter p, and closest approach $R_{min} = q_N$ are shown in units of the semimajor axis of the comet orbit. $\langle\Delta q\rangle$ is the mean change in the pericentre distance of the comets.

Table 2 Maximum perihelion distance of Nemesis

$M_N/M_\odot$	$q_{max}(a_0)$	q_{max} (AU)	e_{min}	P_e	$1-F_N$
0.015	1.7	6,800	0.92	0.15	0.12
0.02	2.1	8,400	0.91	0.17	0.13
0.05	2.6	10,400	0.88	0.21	0.16
0.10	4.0	16,000	0.85	0.27	0.20
0.20	7.4	30,000	0.66	0.60	0.40

e_{min} is the minimum orbital eccentricity of Nemesis required by q_{max}. P_e gives the fraction of the time during which its eccentricity exceeds e_{min}.

Table 3 Change in orbit of Nemesis due to stellar intruders

p/q_N	Ni/Encounter	$\Delta q_N/q_N$	Δq_N/AU	$\Delta p/p_N$
0.1	0.46	0.717	3,200	0.1333
0.2	1.8	0.205	914	0.0559
0.5	11.5	0.080	357	0.0413
1.0	46	0.049	219	0.0102
1.5	104	0.044	198	0.0103
2.0	184	0.020	89	0.0025

p/a_N is the impact parameter in units of the semimajor axis of the orbit of Nemesis. N_i shows the average number of stellar intruders that pass within distance p/a_N of the Sun within one orbital period of 26 Myr. This was scaled from the results given in ref. 4. Δq_N is the change in the pericentre distance per encounter listed in units of the original pericentre distance and in units of AU. $\Delta p/p_N$ gives the average fractional change in the orbital period of Nemesis due to the passage of a single solar mass intruder.

its perihelion distance short enough to allow Nemesis to fill the loss cone of comets with $a_c = 4{,}000$ AU. The number of loss cone fillings is $N = N_0 P_e = 177 P_e$ for these comets. The last column of Table 2 shows $F_L = 1 - F_N$, the fraction of the comets in the inner cloud that have been lost.

I simulated 5,400 encounters between solar-mass stars and the Sun–Nemesis system at an impact velocity of $30\ \mathrm{km\ s^{-1}}$. Here Nemesis is assumed to have a mass of $0.05\ M_\odot$, its orbital semimajor axis is taken as $a_N = 89{,}200$ AU, and its eccentricity is taken as $e_N = 0.95$. Because the impact velocity is much higher than the orbital speed of the Nemesis–Sun system, gravitational focusing is not important and the closest approach of a stellar intruder to the Sun is very nearly its impact parameter. At each of six different impact parameters, p, 900 different simulations were made. None of these 5,400 encounters led to the intruder knocking Nemesis into a hyperbolic orbit. (However, molecular clouds may perturb Nemesis more than passing stars[7,8].)

While most stars are less massive than the Sun and would produce smaller perturbations per encounter than shown in Table 3 (the perturbations in period are proportional to the intruder mass), the large number of stellar encounters per orbital period of Nemesis ensures that at least one star having a mass equal to or larger than the Sun passes within distances $(p/a_N) = 0.5$ per orbital period. This requires that the average minimum change, $\langle \Delta q_N \rangle$, in pericentre distance q_N suffered by Nemesis per orbital period is at least as large as that resulting from an individual star of solar mass passing within distance $p/a_N = 0.5$. Dividing the value of Δq_N in Table 3 by the value of $q_{\max}$ in Table 2, we see that the variation in $\Delta q_N/q_N$ per orbital period of Nemesis must be at least 5% for $M_N = 0.015\ M_\odot$ and about 2% for $M_N = 0.1\ M_\odot$. If Nemesis has a low mass, we can expect fairly large variations in the strength of the comet showers at consecutive perihelion passages. Because of the large number of intruders, we can expect at least one or more intruder of solar mass to approach within distance $p/a_N = 0.5$ of the Sun during each orbital period of Nemesis. The fractional change in the period of Nemesis per orbital period is at least 4%. This can either be an increase or a decrease in the orbital period. After $N = 10$ revolutions the walk-away change in period should be at least 4% $N^{1/2} = 13\%$.

A more disastrous situation than a comet shower would arise if Nemesis were perturbed into an orbit that takes it into the planetary system. In this case, it may strip some planets directly from the Solar System. It would leave the remaining planets in highly eccentric orbits which would produce a fast-moving, dangerous situation[9].

By the Ergodic Hypothesis the time-averaged properties of one object follows the same distribution as an ensemble average over many objects. The fraction of the time that Nemesis spends with a pericentre distance of q_N or less is $F_l = 2q_N/a_N$. For $q_N = 40$ AU and $a_N = 89{,}200$ AU, $F_l = 9 \times 10^{-4}$. As the average change in the pericentre distance, $\langle \Delta q_N \rangle$, of Nemesis per orbital period is much larger than the value of q_N considered, the probability of its entering the planetary system per pericentre passage is 9×10^{-4}. For $N = 177$ pericentre passages, the total probability that it has entered the planetary system is

$$P_N = 1 - (1 - F_l)^N = 1 - (1 - 2q_N/a_N)^N$$
$$= 0.15 \qquad (4)$$

Obviously, this catastrophe did not occur, but the probability is high enough to be interesting.

Nemesis itself may be responsible for the termination of the planetary system at Pluto. If comets formed in the solar nebula just outside the orbit of Pluto, they could have been ejected into the comet cloud by Nemesis. However, the comets may have formed in the outer part of the proto-Sun in the inner comet[4,10–12].

Nemesis may not be the only massive object in the Oört Cloud. However, the fact that the planets have survived in nearly planar, circular orbits indicates that they have not been greatly perturbed since the dissipation of the solar nebula. It is unlikely that any massive object has plunged through the planetary system since its formation. A massive object with a semimajor axis of 2×10^4 AU, that is, one at the inner edge of the Oört or steady-state comet cloud, would have a loss cone $F_l = 2q/a_0 = 4.5$ times larger than that of Nemesis. Its orbital period would be about 0.1 that of Nemesis, so it has made $N \cong 1.7 \times 10^3$ orbital revolutions. Using equation (4) we find that the probability of its having entered within the orbit of Saturn to be about 80%. The lack of apparent damage to the planetary system points to the unlikelihood of their being any massive objects in the inner edge of the Oört Cloud. A Nemesis with a semimajor axis of 9×10^4 AU is dangerous to life on Earth, but a Nemesis at the inner edge of the Oört Cloud would probably have produced a catastrophe of truly cosmogonical proportions.

How stable is an astronomical clock that can trigger mass extinctions on Earth?

Piet Hut

Institute for Advanced Study, Princeton, New Jersey 08540, USA

The periodicity in mass extinctions observed in the fossil record[1,2] may be driven by an astronomical clock consisting of a companion star to the Sun[3,4]. Each perihelion passage of the companion star would result in an enhanced rate of arrival of comets in the inner planetary system, some of which could collide with the Earth and perturb the atmosphere strongly enough to cause a catastrophic extinction of many, if not most, species[5,6]. A similar periodicity has been observed in the cratering rate on the Earth[7,8]. On Earth, the dating of both mass extinctions and crater formation is subject to observational uncertainties. In the heavens, too, we should not expect the 'double star clock' to be perfect, because of the influence of the galactic tidal force field and the perturbations of passing stars. On the basis of orbit calculations reported below, I expect the irregularity in the period of revolution over the past 250 Myr to be at least 10%, and more likely around 20%. This suggests that even completely accurate dating of mass extinctions and crater impacts should not be expected to yield perfectly sharp peaks in the power spectrum of a Fourier analysis.

The present results have been derived from an extensive series of numerical orbit calculations (including 10^7 stellar encounters) the details of which will be published elsewhere. These calculations take into account the perturbations of passing field stars as well as the galactic tidal field on the orbit of a double star; additional perturbations are caused by occasional passages close to molecular clouds and through spiral arms. The first two types of perturbations, stars and galactic tides, act continuously. The galactic tidal field has a nearly constant strength over the orbit of the Sun, and passing stars appear in large numbers: every million years the Sun encounters many different stars some of which actually pass through the orbit of the solar companion. Because of their intermittent character, the effects of molecular clouds and spiral arms are less important on a 250 Myr time scale on which the extinction record is well documented; these will be discussed in more detail elsewhere.

The strongest component of the tidal force acts perpendicular to the galactic plane, where the gradient of the galactic force field is steepest, and has a restoring character. The tidal force in the direction to the galactic centre is smaller by about a factor of six, and tends to pull a wide double star further apart. This radial force is composed of two parts, one of which stems from the radial gradient in the galactic force field and the other from the centrifugal force in the coordinate system rotating with the Sun in its path around the Galaxy. Another important effect in the rotating frame of reference is the Coriolis force acting in the galactic plane perpendicular to the motion of the companion. I have modelled all these effects in a linearized approximation, which is sufficiently accurate[9].

Each field star passing close to the double star exerts a perturbing force which acts over a time interval much shorter than the orbital period of the binary, by a factor typically of the order a few hundred. Therefore, I have used the impulsive approximation, where the perturbing force is taken to act instantaneously at one point in the binary orbit. This approximation saves a factor of nearly 100 in computer time, and gives 1 Myr worth of orbit integration, featuring about 100 stellar encounters, every few seconds (rather than minutes[10]) of central processing unit time on a VAX 11/780 computer.

To understand the relative importance of both types of perturbations, I consider first the galactic tidal field only, neglecting passing stars, and orient the major and minor axes of the orbit along two of the three principal axes of the tidal field. For each of these six choices, I have computed many orbits, all starting with the same eccentricity $e = 0.7$, but with different values for α, the length of the semi-major axis, to find an orbit with a periodicity of 26 to ~28 Myr (Kepler's third law is a poor approximation in the presence of strong tidal forces). The numerical values for the components of the tidal force have been computed from recent estimates at Oort's A and B constants ($A = 16$ and $B = -11$, in km s^{-1} kpc^{-1}, refs 11, 12) together with the inferred mass density in the solar neighbourhood which includes the unobserved galactic disk material[3], while the Coriolis forces follow from the inferred galactic rotation frequency[11,12].

Figure 1*a* shows the largest tidal perturbations which occur for orbits with their major axis perpendicular to the galactic plane and minor axis perpendicular to the direction of the galactic centre (so that the galactic tidal force is purely restoring, which shortens the orbital period and therefore requires a larger, less stable orbit to satisfy a given orbital period). Figure 1*b* shows the most regular orbit, which lies in the galactic plane with its major axis pointing to the galactic centre.

Orbits parallel to the galactic plane are not affected by the strongest component of the tides, and thus are more regular and have a smaller amplitude than orbits which feel the compressive but overstabilizing tidal field component perpendicular to the galactic disk. Both effects suggest that a search for the companion star might have a higher chance of success at lower galactic latitudes (even though crowding is worse there), because (1) the fossil record as well as crater ages are more compatible with the regularity of Fig. 1*b* than with Fig. 1*a*, and (2) the smaller excursions in Fig. 1*b* make the orbit less vulnerable to perturbations by passing stars, which I now discuss.

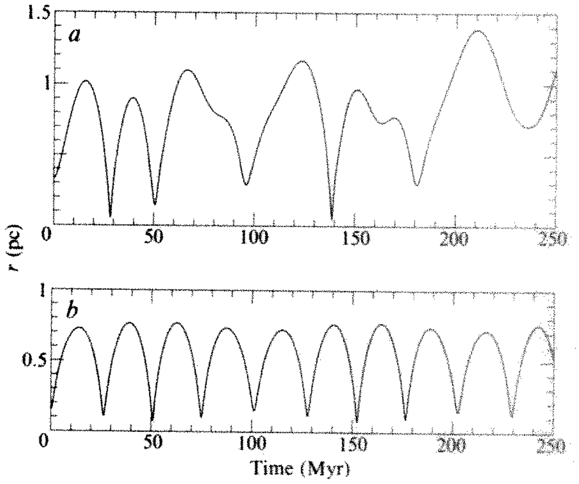

Fig. 1 The separation between the Sun and companion star under the perturbing influence of the galactic tidal field, in parsecs (1 pc = 206,000 AU). *a*, For an orbit perpendicular to the galactic plane; *b*, for an orbit in the plane.

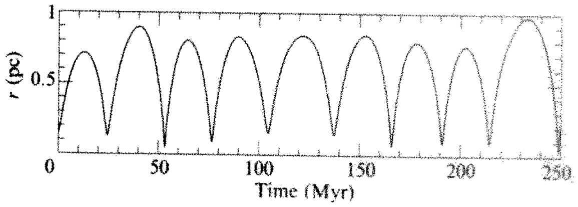

Fig. 2 The separation between Sun and companion star under the combined perturbing influences of passing stars as well as the galactic tidal field, for an orbit with the same initial conditions as in Fig. 1*b*.

I have immersed a double star in a field of passing stars, most of which cause only a tiny perturbation even when they cross the binary's orbit, because the total momentum transfer is proportional to the time spend in the encounter (typically only 0.1–1% of the orbital period). For the distribution of field stars I have accurately modelled the solar environment, using 10 discrete mass classes in the range 0.25–20 $M_\odot$, each with their particular observed number density and velocity dispersion[11,12], with a total mass density of 0.06 $M_\odot$ pc^{-3} (0.02 $M_\odot$ pc^{-3} of which resides in light stars of 0.25 $M_\odot$, to model the unseen disk material; a choice of 0.05 $M_\odot$ pc^{-3} in the form of 0.1 $M_\odot$ stars would have given a similar cumulative effect). The procedure for generating the properly weighted random distributions of orbital elements has been described previously[10] using a Monte Carlo approach to obtain scattering cross-sections in the gravitational three-body problem.

Figure 2 shows an orbit which starts out with exactly the same initial conditions as in Fig. 1*b*, but which is now subject to stellar perturbations as well as to the galactic tidal field. Note the fluctuations in the time intervals between successive close approaches (perihelion passages) of the companion, spanning a range 23 to ~34 Myr. This suggests that even completely accurate dating of mass extinctions and crater impacts should not be expected to yield perfectly sharp peaks in the power spectrum of a Fourier analysis. A more sensitive test of the hypothesis of an unseen solar companion follows rather from the prediction of a tight correlation between individual periods of enhanced cratering rates and periods of mass extinction (several authors have argued that an alternative explanation can be given using the Sun's periodic motion perpendicular to the

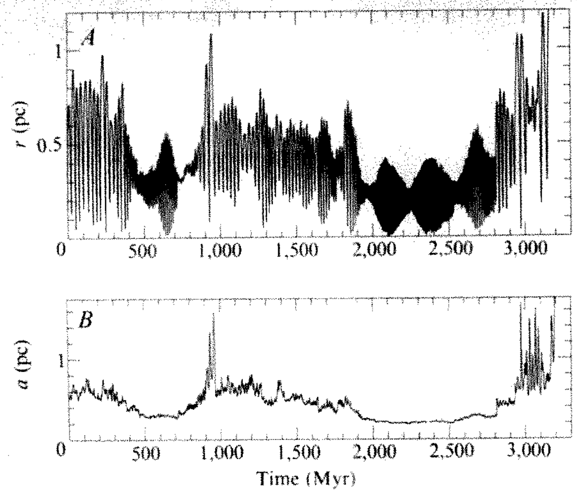

Fig. 3 *A*, The same orbit as in Fig. 2, followed until final dissolution around AD 3,200,000,000. *B*, The evolution of the semi-major axis of the orbit in *a*. The noise in the perturbations has a fine structure down to 0.01 Myr.

galactic plane[8,14]; however, it is hard to understand why both extinctions and cratering seem to occur when the Sun is furthest away from the galactic plane[1,7]). Although the intermediate time intervals cannot be predicted individually, their probability distribution can be obtained from orbit calculations, which thereby provide additional constraints.

Also note in Fig. 2 the significant scatter in the distance of closest approach. The number of comets directed into the inner planetary system at these times is strongly dependent on this distance, although for small perihelion distances a saturation effect might occur if the loss cone is filled completely[3,4]. This could naturally explain why some mass extinctions have been so much more dramatic than others[1,2]. The term 'loss cone' is used in analogy with plasma physics, where a mirror machine has a cone-shaped region in velocity space from which the plasma can escape. For the gravitational application the region in velocity space from which comets are lost is really bounded by a loss hyperboloid-of-one-sheet[15]; this is sufficiently less euphonious that the term loss cone is preferable as long as it is understood to refer to a strictly hyperboloid geometry.

I have computed several hundred orbits, each starting with a revolution period 26 to ~28 Myr, and with an initial distribution isotropic in space. As mentioned above, the orbits parallel to the galactic plane live longer than those perpendicular to the plane. About half of the total sample of orbits dissolved within 1,000 Myr, in agreement with analytical estimates[16-18]. A more quantitative discussion has to include the complicated dependence of the dissolution rate on the orientation of the orbit with respect to the Galaxy, and lies beyond the scope of the present letter. These half lives decrease if the effects of molecular clouds and spiral arms are taken into account, but the decrease is sensitively dependent on the distribution of molecular clouds, which is observationally less well determined than that of the field stars. A realistic guess for the final life time would be a value larger than 500 Myr, because (1) the Sun is, at present, ~1 kpc closer to the galactic centre than on average, and (2) the Sun has an unusually low velocity perpendicular to the galactic plane at present (Wielen, personal communication). Both effects strongly diminish the influence of giant molecular clouds which are concentrated towards the galactic plane and towards the galactic centre, in contrast with results by other authors[18-20]. A detailed analysis of orbit calculations which include these effects will be published elsewhere.

With a half life of 1,000 Myr, survival times of a few 1,000 Myr still occur frequently. Figure 2 shows a double star orbit which lasts for 3,200 Myr, as plotted in Fig. 3*A*, to illustrate the richness of the spectrum of perturbations. The final breakup of the double star occurs after a random walk in orbital parameter space, through the combined influence of more than 100,000 individual encounters with field stars. These perturbations can be seen more clearly in Fig. 3*B*, which plots the semi-major axis a of the orbit. Typically, every 10,000 yr another field star begins an encounter (included in the numerical calculations whenever it occurs within a distance of five times the semi-major axis) each of which lasts for a 100,000 yr. Occasionally a large jump occurs, which can be caused in any of three different ways; the passing star can be extra massive, come extra close or move extra slowly, in each way increasing the total momentum transfer.

The noise in Fig. 3*B* is strongly dependent on the size of the orbit. For $a < 0.3$, on the right-hand side of Fig. 3*B*, the jitter has died down by nearly an order of magnitude. This is because fewer stars pass close to a tighter orbit, and larger perturbations are required significantly to affect a tighter and therefore more energetic orbit. During these lulls in stellar perturbations, the galactic tidal field makes itself visible in the slow modulation of the eccentricity with a period of about 300 Myr, as can be seen in the rising and falling of the amplitude of the excursions in r on the right-hand side of Fig. 3*A*.

The closest encounter in Fig. 3*A* brings the companion to a distance of 800 AU from the Sun, by AD 2,100,000,000. Encounters much closer than that are rare during the lifetime of the Solar System, as I have found from orbit calculations starting at an initial separation of 0.1 pc (resulting in a half life of ~5,000 Myr). This suggests that a planetary system can indeed survive the presence of a distant solar companion, as the expected induced eccentricity for the orbits of the outer planets is <0.01 (ref. 21), even if the companion would come in as close as 200 AU. A detailed study of the perturbations on the planets would nevertheless, be very interesting; it would probably not put very stringent restrictions on the hypothesis of a solar companion, but it might explain the ill-understood irregularities in the planetary system.

Figures 2 and 3 chart only one of the many possible future evolutions of the orbit of a solar companion. Each individual orbit calculation yields vastly different results, since the passing stars exert a stochastic perturbing force on the double star. These perturbations are unpredictable on a short time scale and difficult to treat analytically, even using the average for longer time scales, because of the complicated interference with the galactic tidal field. Each of the different future evolutions which I have calculated as starting with the initial conditions of Fig. 1*b* are equally likely to occur, as are many others starting from different initial conditions (but with the same initial orbital period of 26 to ~28 Myr).

The evolution of the hypothetical solar companion can be summarized as follows: the original orbital period at the time of the formation of the Solar System was probably in the range 1 to ~5 Myr, much shorter than the present value of 26 to ~28 Myr; and the final escape of our companion star might take place relatively soon, on a time scale of the order of 1,000 Myr.

After completing this work I received a preprint by Smoluchowski and Torbett[22], whose calculations of tidal disturbances of comets agree with the present paper.

Orbital stability of the unseen solar companion linked to periodic extinction events

Michael V. Torbett

Department of Terrestrial Magnetism, 5241 Broad Branch Road, NW,
Washington, DC 20015, USA

Roman Smoluchowski

Departments of Astronomy and Physics, University of Texas
Austin, Texas 78712, USA

Recent suggestions of astronomical causes for the closely periodic extinction events in the geological record[1] and the possible periodicities in the cratering record[2] have involved two basic ideas. First, it has been suggested[3–5] that the oscillations of the Solar System through the galactic plane with semi-periods of the order of 30 Myr make possible close encounters with giant molecular clouds, or sub-units thereof, which are expected to scatter Oort cloud comets into the terrestrial zone. Second, it has been suggested[6,7] that a low-mass, and as yet unseen, companion to the Sun, tentatively named Nemesis, is in an eccentric orbit ($e \sim 0.7$), such that perihelion passages bring it through the postulated dense inner Oort cloud[8]. Perturbations of cometary bodies there result in scattering of some 10^9 comets into the terrestrial zone. Those that impact the Earth are assumed to loft dust into the atmosphere, causing climatic chaos[5,9]. To achieve the period that matches the best estimates for the intervals between extinction events, semimajor axes in the range 9×10^4–1×10^5 AU are required. Whether such orbits are indeed stable over the lifetime of the Solar System is not known. We present here evidence from three-dimensional numerical modelling that only orbits with a limited range in inclination with respect to the galactic plane are formally stable for the required length of time. Perturbations bypassing stars and molecular clouds may make even these orbits unstable.

Calculations were done using Cowell's method employing a fourth-order Runge–Kutta integration scheme in an inertial reference frame in orbit about the Galaxy, which is approximated as a point mass of $1.3\times10^{11}\ M_\odot$ at a distance of 8.22 kpc from the Sun to give a galactic rotation velocity of $\sim$250 km s^{-1}. Tidal perturbations in the radial direction due to the Galaxy as well as Coriolis forces are thus automatically included. Superimposed on these forces is the vertical component of the gravitational field of the galactic disk, taken from the results of Bahcall[10] and given per unit mass as

$$f(z) = 2.565\times10^{-11}\,z - 1.66\times10^{-16}\,z^3\ \mathrm{cm\ s^{-2}} \qquad (1)$$

where z is in parsecs. Hence, the companion is subject to the 'gravitational compression shock' during its excursions through the galactic disk. Moreover, since the semi-period of this motion ($\sim$30 Myr) is comparable with the orbital period (26–29 Myr), resonant accumulation of the perturbations can become significant, eventually leading to disruption of the system.

The calculational procedure was as follows. The Sun–companion barycentre was given initial conditions corresponding to a circular orbit about the galaxy with an initial height above the plane equal to that expected for its oscillation amplitude ($\sim$100 pc). The initial inclination with respect to the galactic plane of the companion's orbit was adjusted to yield a resultant mean inclination, i, which was stepped from 0° to 180° in intervals of 10°. During the course of a typical run, the scatter in the inclination amounted to $\sim$10°. The companion and the Sun were then given initial conditions so as to produce a semimajor axis, a, such that the mean interval between perihelion passage was in the range 25–30 Myr and eccentricity, e, in the range such that perihelion passage occurred within the inner Oort cloud. To achieve the proper period, it was necessary to vary considerably the semimajor axis due to the strength of the perturbations relative to the solar attraction at the separation required. Values of 10^{-1} and $10^{-2}\ M_\odot$ for the mass of Nemesis were both investigated, with negligible differences in the results.

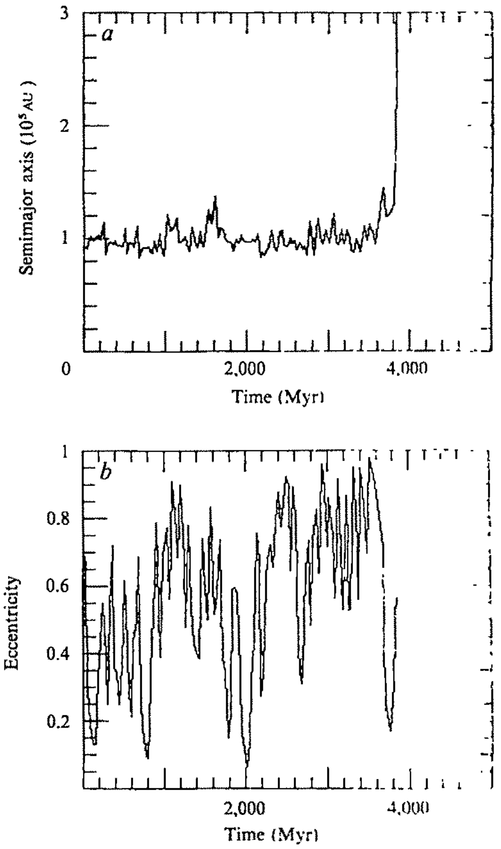

Fig. 1 *a*, Semimajor axis and *b*, eccentricity as functions of time for Nemesis in an orbit about the Sun inclined at an angle $i_0 = 40°$ with respect to the galactic plane. System becomes unstable within the age of the Solar System.

The results indicate that for inclinations $i \gtrsim 30°$ the orbits are unstable with the system being disrupted within the age of the Solar System. This is true for both prograde and retrograde orbits. A representative case is illustrated in Fig. 1 where a and e are plotted as a function of time for $i \sim 40°$. Orbits with larger values of inclination than shown in Fig. 1 become unstable even sooner. For example, at $i \sim 90°$, the system is disrupted within 500 Myr. For inclinations $i \lesssim 30°$ the orbits appear stable although irregular as shown in Fig. 2 where a and e are again plotted as a function of time. Orbits with high galactic inclination are less stable than low inclination orbits since the vertical tidal field of the disk is 3 or 4 times stronger than is the radial galactic tide at the Sun's position. Thus, inclined orbits sense stronger perturbations than do orbits lying in the plane. This leads to more chaotic trajectories for the inclined case as can be seen by comparison of Figs 1 and 2. Hence, since the orbits with periods corresponding to extinction intervals verge on the margin of stability[11], the near-resonant match of orbital period with

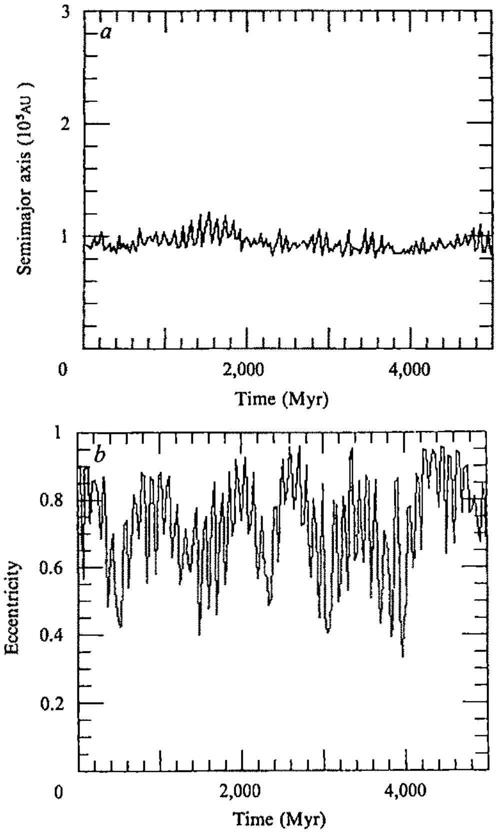

Fig. 2 *a*, Semimajor axis and *b*, eccentricity as functions of time for Nemesis with galactic inclination $i_0 = 30°$. Orbit is formally stable for the age of the Solar System, although irregular.

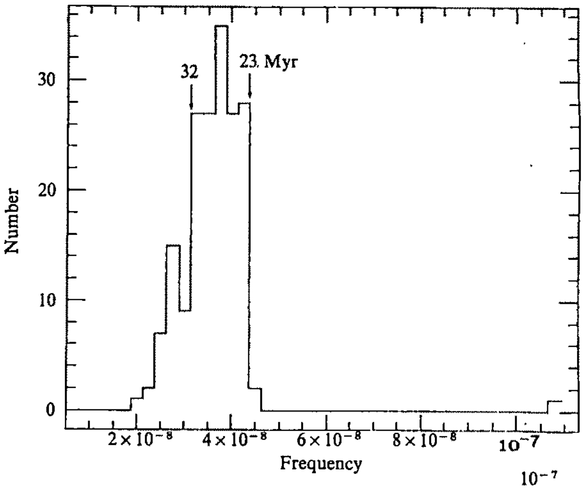

Fig. 3 Histogram of the inverses of the intervals between perihelion passage for prograde orbit of Nemesis for the case depicted in Fig. 2. Note the scatter in the intervals from 23 to 32 Myr. Thus strict periodicities should not be expected in fossil or crater records.

the semi-period of the Sun's oscillation about the galactic plane leads to disruptive accumulation of perturbations.

Figure 3 shows a histogram of the inverses of the intervals between perihelion passage for the case shown in Fig. 2. It is clear that the intervals vary widely within limits greater than the 25–30 Myr inferred from the data. This chaotic nature of the permitted direct orbits makes the causal connection of periodic extinctions with regularly timed astronomical events less compelling. Retrograde orbits with $i < \sim 30°$ seem, however, to be considerably more stable because in this case Coriolis forces tend to increase rather than decrease stability. This results in the range of the limits for intervals between perihelion passage being factors of 2–3 smaller than in the prograde case and within the limits of the data. Thus, the scatter in orbital period can be reduced by assuming a retrograde orbit for Nemesis. Hence, if Nemesis exists, it may be in retrograde orbit; but even then, strict periodicities should not be expected even in perfectly dated fossil records. These results indicate that orbits for the companion that are inclined at more than 30° to the galactic plane are not allowed and suggests that the search for Nemesis should be concentrated towards the plane of the galaxy. This limit on the range of permissible galactic inclinations excludes orbits in the plane of the ecliptic, which makes an angle of ~60° with the galaxy. It is not impossible, however, that an orbit originally in the ecliptic could have been perturbed to lie near the plane of the galaxy by close encounters of passing stars or molecular clouds.

Perturbations by passing stars or molecular clouds may make even the low-inclination orbits unstable. Stability analysis[12] of companion orbits subject to stellar perturbations and the galactic tides, while neglecting the 'gravitational compression shock' due to the vertical oscillations, indicates lifetimes for Nemesis of the order of 10^9 yr which is consistent with our analysis. In addition, the randomizing effect of stellar perturbations on the orbital elements will change low-inclination orbits into high-inclination ones leading to disruption. Perturbations by molecular clouds may, however, deliver the most serious blow to stability. Numerical modelling[13] of the effect of molecular cloud passages on cometary orbits indicates that for close encounters a large fraction of the orbits will be disrupted. Preliminary analysis from a current numerical study (Torbett, M. V. & Smoluchowski, R., in preparation) shows that, for the expected encounter distances from, and velocities relative to, $10^5 M_\odot$ clouds, a large fraction (>50%) of the orbits for Nemesis will be disrupted. This is in reasonable agreement with arguments based on balancing the tidal force of the cloud against the binding force.

Hence, at best, the existence of an appropriately positioned companion should be viewed as a highly temporary, low-inclination, and probably retrograde phenomenon. At worst, the instabilities induced by the galactic tides and molecular cloud passage make the companion hypothesis untenable.

Nitryl perchlorate as the essential intermediate in the thermal decomposition of ammonium perchlorate

Andrew K. Galwey & Mohamed A. Mohamed*

Department of Chemistry, The Queen's University of Belfast,
Belfast BT9 5AG, UK

Because of its use as a solid propellant and more generally in pyrotechnic systems, the thermal decomposition of ammonium perchlorate (AP) has been extensively studied. The breakdown of this salt is complicated, an exceptional feature being that the low-temperature (<~570 K) decomposition is incomplete

---

* Permanent address: Department of Chemistry, Faculty of Science, Assiut University, Qena, Egypt.

(~30%), yielding a residual solid with a composition and crystal structure very similar to those of the original reactant. Extensive rate measurements and kinetic analyses[1-5] have produced two alternative general hypotheses of reaction mechanisms[5], in which rate control has been attributed to steps involving the transfer of either a proton[4] or an electron[6]. In the present study, we have found that the addition of various inorganic nitrates reduces the induction period to reaction and increases the extent of the low-temperature decomposition of AP. The measured rate of decomposition was close to that estimated for reaction involving nitryl perchlorate (NO_2ClO_4) as an intermediate and we have detected small quantities (~0.08%) of an oxidized nitrogenous species in partly reacted AP. We therefore propose a novel reaction mechanism in which NO_2ClO_4 is the essential intermediate in the thermal decomposition of ammonium perchlorate.

Our investigation of the possible rôle of oxidized nitrogen in promoting AP decomposition represents an attempt to characterize the chemical steps involved in breakdown of the relatively stable (at ~500 K) perchlorate ion, ClO_4^-. Khairetdinov and Boldyrev[5] have pointed out that the present reaction, involving sublimation, occurs 300-350 K below the corresponding temperatures for reactions of other alkali perchlorates. Perchloric acid is sufficiently stable to survive sublimation and it is suggested that the low-temperature reaction may be incomplete due to accumulation of the relatively more stable acid hydrates, $H_3^+O\ ClO_4^-$, $H_5^+O_2\ ClO_4^-$, etc., on the walls of the channels eroded in the reactant crystals during decomposition. We have attempted to identify the intermediates involved in these reactions and the interactions that culminate in ClO_4^- disintegration.

It is known that ammonium salts of certain strongly oxidizing anions yield NH_4NO_3 on decomposition[2] and that the same compound, NH_4NO_3, reduces the induction period to AP reaction. The formation of N_2 and N_2O during AP decomposition[2] can be explained by the intervention of nitrite and nitrate respectively, involving a mechanism generally similar to that recently proposed[7] for the breakdown of $(NH_4)_2Cr_2O_7$. At least one other type of additive containing oxidized nitrogen—nitrophenol-formaldehyde polymers—has been shown[8] to accelerate AP breakdown. Oxidized nitrogenous species thus appear to merit particular consideration as intermediates.

We made isothermal kinetic studies of the decomposition of AP alone and with added NH_4NO_3 or $Mg(NO_3)_2 \cdot 6H_2O$, both of which readily melted on heating to reaction temperature. Comparative yield-time data for N_2+O_2 evolution (in a conventional accumulatory apparatus[3] using a 78 K refrigerant trap) during the low-temperature reaction[2] for consecutive experiments, in identical conditions, showed that both additives significantly reduced the induction period to reaction. Figure 1*a* shows typical results for the decomposition at 495 K of AP by itself and initially covered with molten NH_4NO_3 (most of which was rapidly volatilized out of the reaction vessel soon after the start of the reaction). The additive markedly reduced the induction period (from 120 to 40 min) and appreciably increased the reaction rate (by about 1.5 times) but it did not change significantly the final yield of product gases (N_2+O_2).

Figure 1*b* shows the relative activities of four different inorganic nitrates in promoting the decomposition of AP powder at 503 K. Three of the additives (NH_4^+, K^+ and Mg^{2+} nitrates) caused approximately similar reductions in the time to onset of reaction. The ammonium salt was the most effective of this group, however, in accelerating the overall rate of reaction, presumably because removal by distillation occurred less readily here and volatilization temporarily distributed the additive to all surfaces of the compacted powder reactant. Systematic variations in the proportion of added $Mg(NO_3)_2 \cdot 6H_2O$, between 1 and 25%, showed that the kinetic characteristics did not vary widely from the curve shown in Fig. 1*b*, but the total yield of gaseous products (N_2+O_2) was always greater than that obtained from the pure salt. Silver nitrate was identified as being a particularly active catalyst for AP decomposition, causing the most rapid onset of reaction and the greatest increase in rate of decomposition.

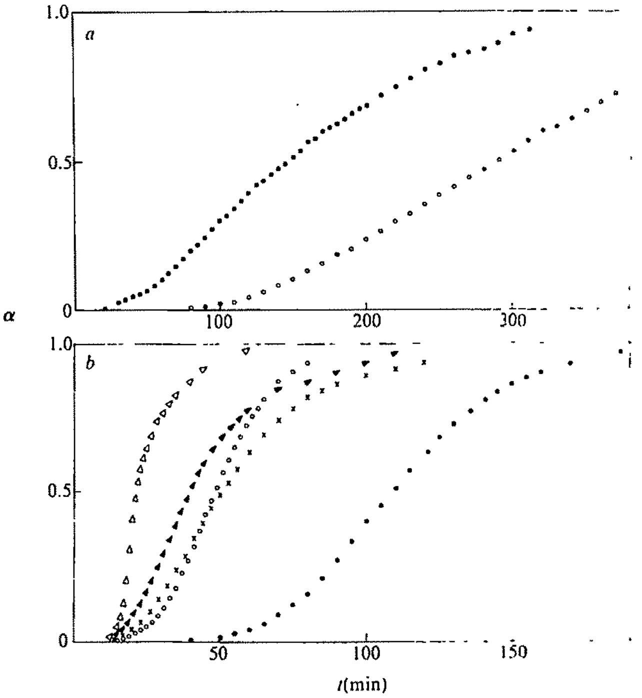

Fig. 1 *a*, Curves of comparative fractional reaction (*α*) against time for the isothermal (495 ± 1 K) decomposition of single crystals of AP measured for evolution of N_2+O_2 (78 K trap) in identical conditions in a constant-volume system. One crystal was reacted 'as prepared' (○); the other was 'promoted' by the addition of NH_4NO_3 (●), which resulted in a reduction of the induction period and an increase in the reaction rate. *b*, Comparative *α*-time curves for the decomposition of AP powder mixtures crushed with 10% (by weight) of various nitrates: NH_4NO_3 (○), $Mg(NO_3)_2 \cdot 6H_2O$ (▲), KNO_3 (×), $AgNO_3$ (△), and no additive (●). All four additives reduced the induction period, accelerated the maximum rate of reaction and increased the extent of reaction. The silver salt was the most active catalyst. The reactant mixtures containing nitrate and AP were crushed in a pestle and mortar before reaction.

Microscopic inspection of large single crystals after partial (≤10%) decomposition, initiated with either added NH_4NO_3 or $Mg(NO_3)_2 \cdot 6H_2O$, showed that the reaction was initially rapidly established over the entire surface of the AP reactant, in contrast to the well known development of individual, approximately hemispherical nuclei during reactions of unpromoted single crystals[2]. The same conclusion was reached on scanning electron microscope examination of cleavage surfaces traversing reacted zones, exposed after the partial decomposition of large single crystals. Representative textures are shown in Fig. 2*a*,*b* for an exposed cleavage section of an AP crystal after 10% decomposition initiated by adding $Mg(NO_3)_2 \cdot 6H_2O$. A continuous layer of decomposed salt, with approximately constant thickness, has developed below the original crystal surface; this contrasts with the generation of separated reaction zones (nuclei) during reactions of the salt in the absence of additives: the edge of a discrete nucleus and a zone of unnucleated surface are evident (Fig. 2*c*).

Previous observations[3] have shown that the yield of gaseous products (N_2+O_2) by a second successive AP decomposition is ~10% that of the first. Here we have repeated this observation and have also shown that the addition of NH_4NO_3 to a decomposed crystal, followed by the restoration of reaction conditions (510 K), results in a marked increase in the extent of the second reaction, to ~50%. This demonstrates the ability of the nitrate to promote AP decomposition.

Previous analytical measurements have detected NO_3 in partly decomposed AP[9] and in the sublimate[2]. We have measured the amount of oxidized nitrogen in partially (50%) decomposed AP by two methods: first, by reaction with brucine[10] in sulphuric acid, followed by spectrophotometric determination of absorption at 405 nm, and second, by the (less accurate)

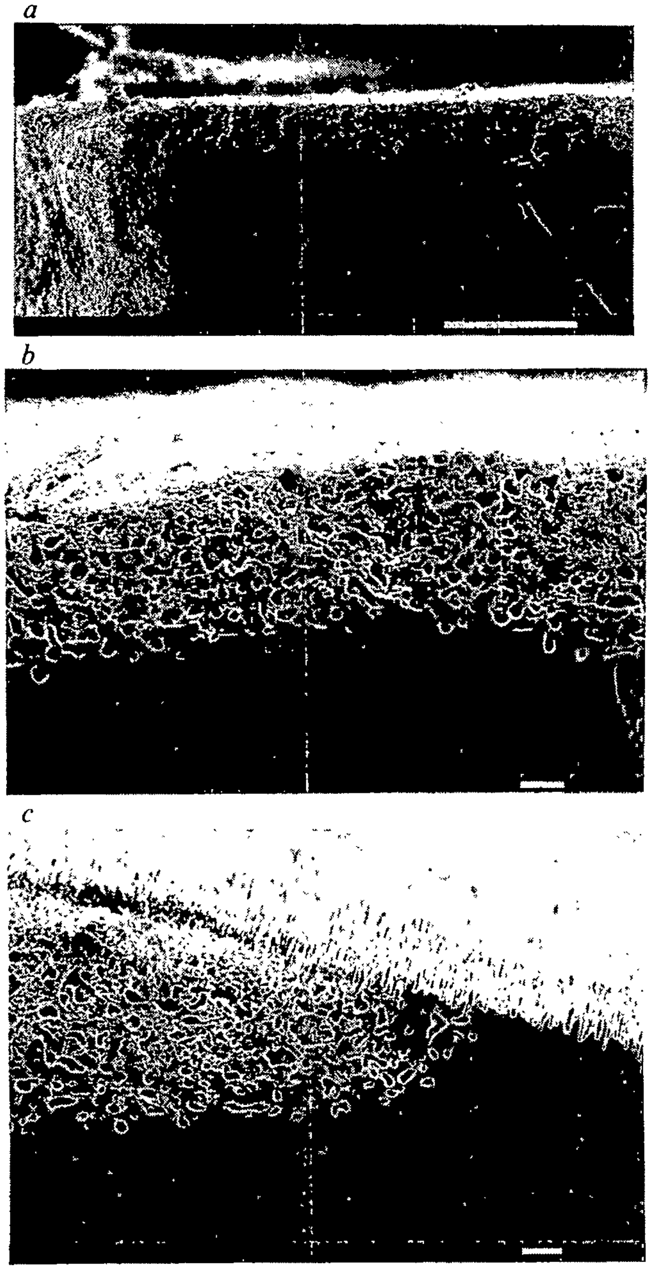

Fig. 2 Scanning electron micrographs of decomposition zones, revealed in section by cleavage of single crystals after 10% reaction. *a*, *b*, The reaction in this crystal was initiated by addition of $Mg(NO_3)_2 \cdot 6H_2O$, which melted immediately on heating. The decomposed layer is of almost constant thickness and is developed below the total surface. *c*, In reaction of the pure salt, discrete nuclei were formed; the boundary edge of one of these is shown here. Although reaction has not occurred in the crystal beyond the nucleus, the surface is extensively grooved. Scale bars (white): *a*, 100 µm; *b*, *c*, 10 µm.

colorimetric method as ammonia with Nessler's reagent (after removal of ammonia by boiling with alkali, followed by reduction with Devarda's alloy). While the low concentration of the active intermediate present precludes its specific identification (as NO_3^- or NO_2^+), repeated determinations gave reproducible evidence that the amount of oxidized nitrogen present corresponded to 0.08 ± 0.04% NO_2ClO_4. (This choice of intermediate anticipates the conclusion reached in our mechanistic discussion below.) The quantities of oxidized nitrogen detected in the residual salt[9] and in the sublimate[2] were less, corresponding to ~0.01 and ~0.02% NO_2ClO_4, respectively.

It seems probable that nitrate present during decomposition under the oxidizing, acidic[2,5] and probably dehydrating conditions prevailing within the reaction zones must be in the form NO_2ClO_4 (ref. 11). Nitryl perchlorate, therefore, is identified as the reaction intermediate as it is unstable at reaction temperature[11,12] and its presence can be maintained by dynamic equilibrium through ammonia oxidation by the active oxygen species resulting from ClO_4^- breakdown. NH_3 and/or NH_4^+ reacts with products of ClO_4^- disintegration to yield NO_2^+ which combines with a reactant anion and, on decomposition, the cycle continues.

In this mechanism, the difficult perchlorate ion breakdown step is explained by the formation and rupture of covalent bonds, as such perchlorates are less stable[13] than the more ionic compounds:

$$O_2N^+ + OClO_3^- \rightarrow [O_2N{-}O{-}ClO_3] \rightarrow [O_2N^+O] + ClO_3^-$$

The unstable $[O_2N^+O]$ may rapidly, perhaps concurrently, disintegrate, yielding $N^+O + O_2$ (or 2O); $NOClO_4$ is also a product of NO_2ClO_4 decomposition[11]. The chlorate ion is known to be unstable under reaction conditions[5] and capable of oxidizing NH_3 and/or NH_4^+ since NH_4NO_3 is a product of NH_4ClO_3 decomposition[2].

We estimate, by extrapolation of published[12] kinetic data, that decomposition of NO_2ClO_4 at 503 K would proceed from 20% to 80% in 0.10 min. At 50% reaction, our powder samples of AP reactant contain 0.08% NO_2ClO_4. For this dynamic equilibrium concentration of intermediate and estimated reaction rate, we calculate, by direct proportions, that the time required to complete the low-temperature (503 K) rate process (30% AP weight loss) is ~70 min. The corresponding time estimated from the middle section of the curve for AP powder in Fig. 1*b* is ~85 min. In view of the uncertainties in our calculations, this agreement is unexpectedly close and provides strong evidence that the NO_2ClO_4 decomposition step is rate-controlling in AP decomposition. (The similarly estimated[14] value for NH_4NO_3 decomposition is larger, and less attractive here because it does not result in ClO_4^- breakdown.)

In the kinetic argument presented above, we have not considered the phase within which the NO_2ClO_4 decomposes. If this intermediate is present as a solid, geometric controls may be expected to operate[15]. However, it is known that NO_2ClO_4 is volatile[11] at reaction temperature, though here confined within the pores of the reaction zone, and its melting point may be depressed by eutectic formation with the other perchlorates present (NH_4ClO_4, $HClO_4$, $NOClO_4$). It seems probable, therefore, that reaction occurs in local melted droplets (fusion nuclei[15]). Evidently, the concurrent oxidation of ammonia and the presence of hydrogen-containing products does not significantly affect the rate of decomposition of the NO_2ClO_4 intermediate. We also note that the activation energy for AP decomposition[1-4] is close to that[11,12] reported for NO_2ClO_4 (130 kJ mol^{-1}), which provides a further indication that the same rate-controlling process operates in both reactions. This similarity is not, however, a proof of mechanism because the same value has also been reported[16] for the breakdown of $Cl_2O_7(+H_2O \rightleftharpoons 2HClO_4)$, another covalent molecule. Thus, this temperature coefficient of reaction may be characteristic of the common step, the bond rupture: $O{+}ClO_3$.

The internal structures of zones of decomposed salt (nuclei), revealed by cleavage section after reaction, were identical in the pure salt and following initiation by NH_4NO_3 (Fig. 3*a* and *b*, respectively) or $Mg(NO_3)_2 \cdot 6H_2O$. This is evidence that the additive does not change the mechanism and is consistent with the view that promotion involves the conversion of NO_3^- to NO_2^+, which thereafter participates in the chemical sequence described above.

Each pore in the reacted salt (~0.2–0.5 µm diameter) evidently resulted from the irregular progress of an active droplet of NO_2ClO_4, and the rounding of these internal surfaces provides further indication of the participation of a fluid or molten reaction phase. The larger holes, up to 5 µm diameter, and

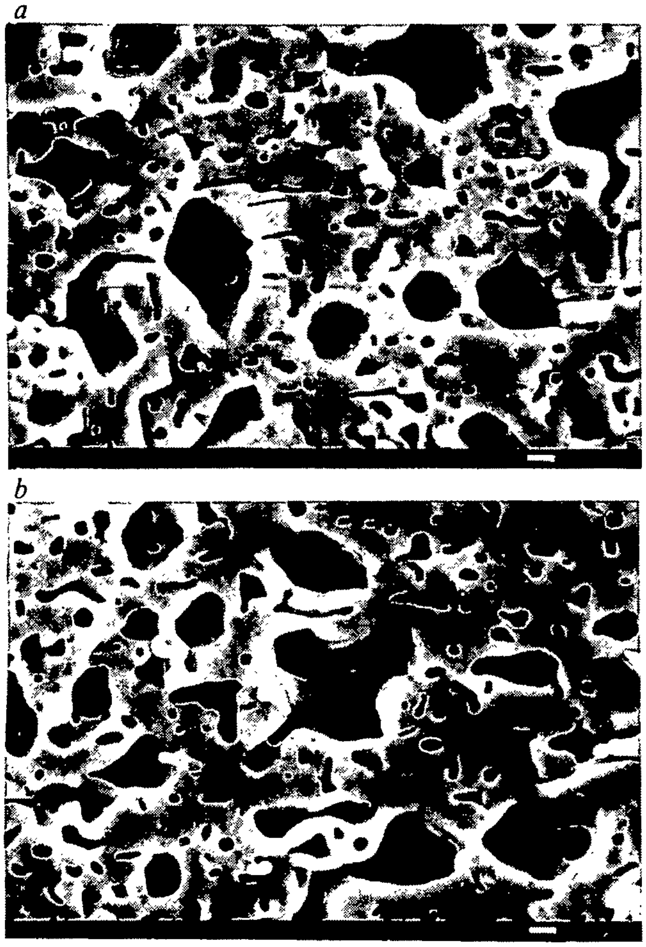

Fig. 3 Scanning electron micrographs showing cleavage sections of decomposed regions of AP in *a*, a pure crystal and *b*, a crystal in which the reaction was initiated by NH_4NO_3. No difference in texture could be discerned in a series of careful comparisons of many areas of both types. We suggest that the texture of the decomposed salt is that of reactant remaining after penetration by the irregular migration of small particles of an active phase within or around which decomposition occurs, presumably including NO_2ClO_4 intermediate and possibly in the form of liquid. Enhanced reaction occurs when droplets coalesce, resulting in the larger pore spaces. Scale bars, 1.0 μm.

evidently linked by two or more pores, may be ascribed to a marked enhancement of reaction when two active reaction droplets meet during their irregular wanderings. Perhaps there is temporary growth of the active reaction zone by bubble or froth formation. As nuclei grow hemispherically, there must also be division of active droplets[17] into two or more which thereafter progress independently. Unfortunately, the identification of the distribution of NO_2ClO_4 within partly decomposed crystals was impracticable as it hydrolyses so readily.

The reaction mechanism described above does not take into account the initiation of reaction in pure AP, where no source of oxidized nitrogen is available. Although we have not yet studied in detail the slow reactions occurring during the induction period, we have observed that nucleus generation often occurs within grooves on roughened surfaces (see, for example, Fig. 2*c*). Such surface retexturing occurs during sublimation and presumably is accompanied by other slower decomposition reactions, such as Cl_2O_7 breakdown[16], capable of oxidizing ammonia. Any volatile NO_2ClO_4 produced can only participate in nucleus growth when it is effectively retained within pores and channels, progressively formed at the inner surfaces of grooves. Thus again[17,18] we identify nuclei as specialist structures developed particularly to retain (temporarily) a fluid participant in the chemical change. Salt that is undecomposed after passage of active liquid droplets occurs because sites of enhanced reactivity have been removed and further intermediate cannot be produced in sufficient local concentration to generate a new reaction zone. The addition of NH_4NO_3, however, was capable of initiating some further decomposition of the residue.

This mechanism can also explain the ability of certain compounds to act as catalysts for AP decomposition. NH_4ClO_3 yields[2] NH_4NO_3, shown here to be active in promoting AP decomposition. Permanganate and chromium-containing[7] anions may participate similarly by oxidizing ammonia, the reduced oxyanion being reoxidized through ClO_4^- breakdown.

We thank J. McCrae and R. Reed for advice on obtaining and interpreting the electron micrographs. M.A.M. thanks the Egyptian Government and the ORS Award Schemes for Scholarships held during this research.

South African modern beach sand and plate tectonics

Paul Edwin Potter

H. N. Fisk Laboratory of Sedimentology, Department of Geology, University of Cincinnati, Cincinnati, Ohio 45221, USA

South America is the ideal continent for baseline studies on how the framework composition of modern sands relates to reconstruction of palaeoplates—it has well-defined active and passive margins, great contrasts in climate and relief and is free of continental glaciation (Fig. 1). I report here petrographical studies of its beach sands which show two active margin associations rich in volcanics and plagioclase—one along its Pacific coast and one along the Argentine coast—and two associations rich in quartz—a passive margin association from Argentina to Trinidad and a moderately, quartz-rich association along the Caribbean coast. Tectonic control is thus overwhelming but complications exist along the Argentine coast where a dry, narrow continent permits active margin sand to mantle a passive margin. Another surprising result is that quartz-rich sands border the crystalline rocks of much of the Sera do Mar in Brazil.

Sandstone has long been used[1] to help identify the tectonic setting of ancient basins for many reasons. It is present in almost every basin, including some of the very oldest, and it occurs in almost every sedimentary environment with the possible exception of the abyssal plains of some deep sea basins. Each grain also carries its own provenance history, which is easy to study with both microscope and microprobe. However, the idea that the petrographic study of 10–30 sandstone samples from an ancient basin, perhaps a sample of only 10^{-12} to 10^{-16} of its entire volume, can reveal a plate tectonic setting, and thus infer major crustal processes, may be considered audacious.

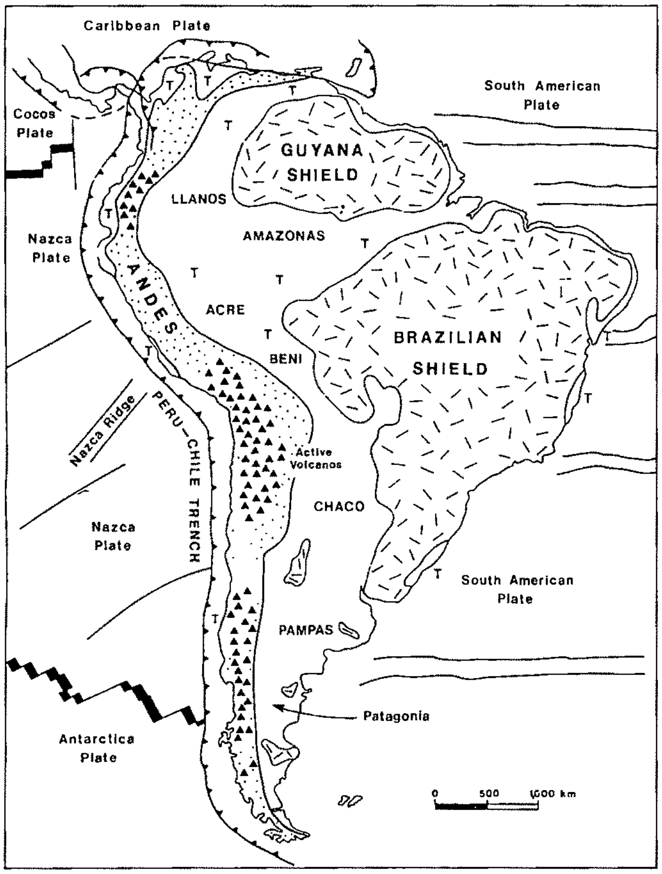

Fig. 1 Major tectonic elements of South America and adjacent ocean basins.

Present themes of the plate tectonic control on framework mineralogy come from studies of Mesozoic and Cenozoic basins[2–7] supplemented by studies of modern deep sea[8–11] and alluvial sands[12–15]. More than 40 papers on the plate tectonic interpretation of sandstone mineralogy have appeared since 1970, and virtually all of these recognize three different major tectonic settings with seven to nine subdivisions using standard compositional triangles (Fig. 2).

South America, the fourth largest continent, forming 12% of all the Earth's land surface, is the most elegantly asymmetric of all the continents from a plate tectonic standpoint—the entire west coast is an active margin, all of the eastern coast from Tierra del Fuego to Trinidad is a passive margin and only its Caribbean border, where translation seems important—is moderately complex (Fig. 1). South America is also free of continental glaciation; continent-wide provenance studies of modern sands are difficult to interpret where Pleistocene continental glaciation was widespread, because it blurs the continent-wide distribution pattern of sand. The climate of South America ranges from arid, with extremely dry deserts along coastal Peru and Chile, through temperate to tropical, with up to 10 m of rainfall in northwestern Colombia. Furthermore, major climatic trends are transverse to the Andes. Physiographic contrasts are equally impressive. The Andes Mountains, the world's longest mountain range with a length of almost 9,500 km, have towering peaks, an average elevation second only to that of the Himalayas, and many high, vast, dry plateaus. Additionally, South America has sweeping plains and low plateaus—some dry and grass covered, some covered by vast jungles. Also present along much of the Brazilian coast are jungle covered mountains composed of Precambrian rocks that rise from a narrow coastal plain. The coastal physiography and climate for the entire continent is summarized in ref. 16.

Another reason to study South America is that there are data available on the petrography and chemistry of the modern river sands of the Amazon and Tocantins basins[14], an area that covers about 40% of South America plus some for the Magdalena, Orinoco, Parniba do Sul, Paraná and Sao Francisco rivers[15], as well as for small rivers on the Peruvian coast. Together these river sands come from basins that drain about 65% of the continent. There are also published data on deep-sea and shelf sands of the Peru–Chile trench bordering South America[17] in addition to the sands of Atlantic shelf[18].

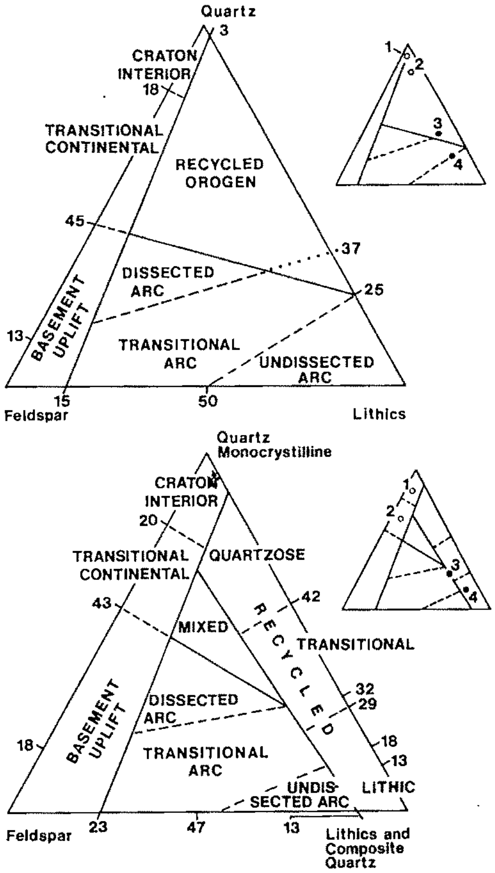

Fig. 2 Plate tectonic classification of sandstone mineralogy (after ref. 6, Fig. 1). Numbers in the small triangles indicate: 1, average composition of passive margin sands from the Rio de Plata to Trinidad; 2, beach sands from Trinidad westward along the Caribbean coast; 3, Argentine beach sands; and 4, the sands of South America's Pacific coast (see Fig. 3).

This study reports on the first-ever effort to study petrographically the sand of a single environment, the beach, around an entire continent. The technique used in sampling the beach sands of South America was based on that of Du Rietz[19], who showed how the petrology and chemistry of modern Baltic beaches become more mature as litoral drift transports sand away from the southern edge of the Baltic Shield.

Why study modern beaches? The beach is the interface between marine and non-marine environments so that all marine sands have passed through it and, with recycling, perhaps the same is true for many, if not most, ancient sandstones. Because the beach environment is one of high kinetic energy, it provides a strong test of another factor: modification of framework mineralogy by abrasion. In other words, if petrologists can correctly identify the tectonic setting of a landmass from its beaches, surely they could do so from its fluvial sands. Also, the beach is an easy environment to reach and sample—an important factor when an entire continent with a coast line of 50,000 km is to be sampled. More than 200 samples of beach sand were collected in 116 field days. Beaches were selected at points of convenient access and the 27 samples reported here were selected because of their geographical representation of each major mineral association.

Where possible, fine- to medium-sand was collected to best match the dominant size classes with midpoints of 177 and 350 mm (2.5 and 1.5ϕ) as reported by Shea[20] based on his compilation of 11,212 analyses chiefly of onshore sands and sandstones, but including some sands from modern continental shelves. These two size classes include ~35% of his present average grain-size distribution. Because grain sizes of samples in this study are coarser than those of most deep-sea sands, more rock fragments with their greater provenance information can be expected than in studies of typical fine-grained, deep-sea sands derived from the same source. To avoid the pitfalls of studying only a narrow size fraction and missing important diagnostic grains[21], the entire sand was impregnated and studied using standard counting procedures[15] after staining for potash feldspar.

Contrasts in the beach sands of South America are dramatic as judged by variations of quartz (Q), feldspar (F), and rock fragments (Rf) and dominant types of rock fragments (Fig. 3). Beach sands of South America's leading margin, the Pacific coast, have an average Q:F:Rf ratio of 19:13:68, whereas the continent's trailing margin coastline from the Rio Plata to Trinidad, a coastline bordering the Brazilian and Guyana Shields, averages 95:3:2, a staggering difference which is even more impressive when it is realized that mountains composed of Precambrian crystalline rocks border much of the South Atlantic coastline of Brazil. A petrographical count of each size fraction from a beach at Huacho in Peru and one from Natal in Brazil confirm these contrasts (Fig. 4). Downstream increase in quartz content in both the Amazon and Orinoco rivers effectively eliminates significant Andean contributions to beach sands from the mouth of the Amazon to Trinidad (Fig. 5). The rock fragments of the two major mineral associations are also totally different—volcanics predominate along most of the Pacific coast whereas rare alterites and igneous and metamorphic grains are characteristic of beach sands between Rio de la Plata and Trinidad.

Two smaller mineral associations are present and both are of great interest. All the Argentine coast from Rio de la Plata to Tierra del Fuego has an Andean, leading edge composition only slightly more mature than that of Pacific beach sands—the Q:F:Rf ratio averages 33:15:52—and again volcanics are its dominant rock fragments. Although the entire Argentine coast is a trailing margin, its beach sands have a leading edge composition because Patagonia is narrow and its bedrock near the coast is largely Tertiary molasse itself derived from the Andes. In addition, rainfall is scant, thus minimizing increase in maturity downstream from the Andes. One important implication immediately follows—use of sandstone mineralogy alone to identify palaeoplate setting can result in tectonic misclassification unless the basin's characteristics and regional setting are also considered.

The fourth and smallest association occurs from Trinidad to the mouth of the Magdalena River in Colombia. Here beach sands have an average Q:F:Rf composition of 78:5:17, although locally rock fragments are more abundant. This predominance of quartz—as along the southwestern coast of Brazil—is surprising given the proximity of metamorphic highlands close to the horeline. Dominant rock fragments are metamorphics derived from the Venezuelean Andes.

Preliminary results based on thin section study of light minerals indicate four major mineral associations for South American beaches: two immature leading edge associations and two trailing margin association, one from the Rio de la Plata to Trinidad and the other along the Caribbean coast from Trinidad to the Magdalena River. Compositionally, west coast beaches plot on the boundary between undissected and transitional arc of Dickinson and others[6] and Argentine beaches plot as a recycled orogen (back arc basin), although near the boundary to transitional arc; Venezuelan beaches plot as a recycled orogen near the boundary of the craton–interior field and beaches from the Rio de la Plata to Trinidad plot in the craton–interior field (Fig. 2, inset). Thus my preliminary results confirm the fields suggested by Dickinson and others[6].

These preliminary results pose several interesting questions: Where a leading edge of a continent becomes narrow, its

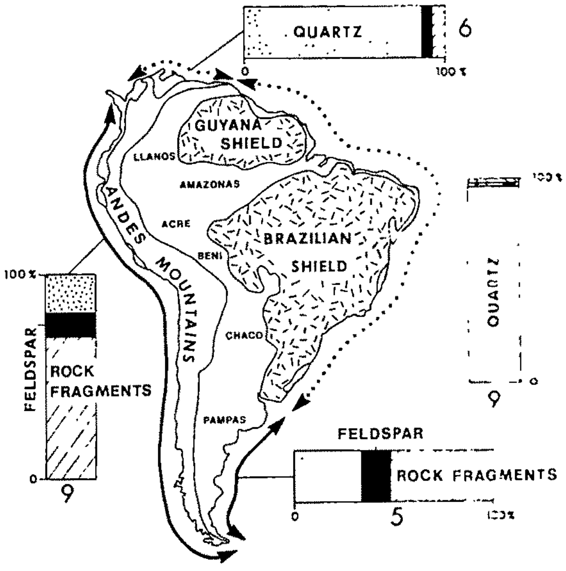

Fig. 3 Major, broad, mineral associations of South American beach sands.

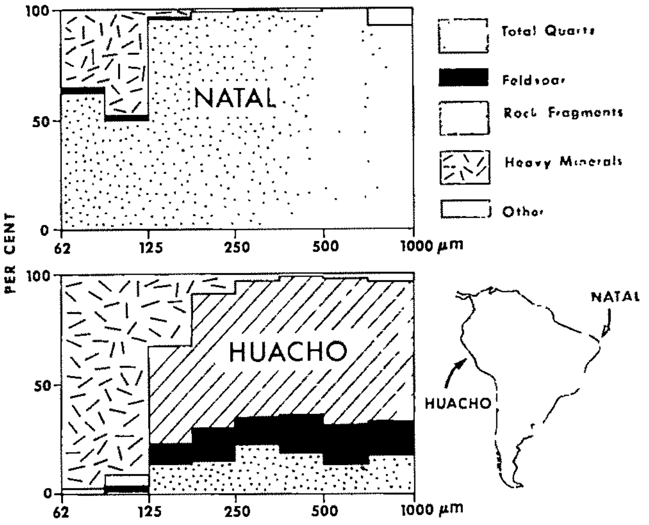

Fig. 4 Fraction analysis of beach sand at Huacho, Chancay Province, Peru and Natal, Rio Grande do Norte, Brazil shows great contrast in composition between each size grade.

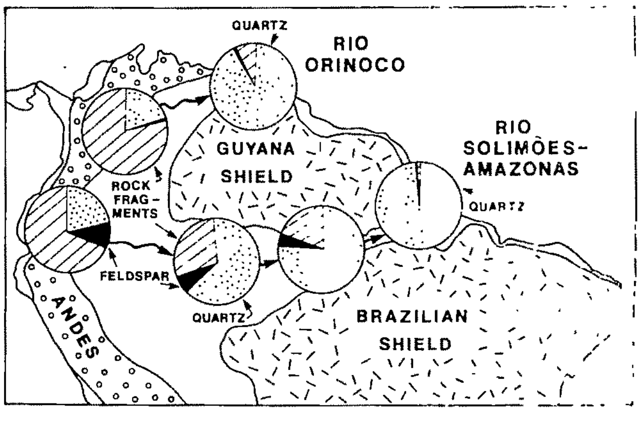

Fig. 5 Downstream increase in compositional maturity—more quartz and fewer rock fragments—in Orinoco and Solimões–Amazonas Rivers. Data for Solimões–Amazonas from ref. 14

characteristic composition can also occur on its 'backside', passive margin, especially where a dry climate prevails, as in Patagonia in Argentina. What implications does this have for the palaeogeographic reconstructions of ancient basins? How will a wet versus dry climate on the backside of a continent affect the mineralogy of its sandy detritus reaching the sea?

Abrasion on the beaches of South America's western leading edge does not reduce our perception of the towering land mass on shore; on the other hand, the low feldspar content of beaches bordering Brazil's Serra do Mar commonly gives little hint of these Precambrian mountains. Would this be true if the coastal climate were arid rather than humid?

Why do some of the continent's larger rivers show such a great change in mineralogy from Andean source to Atlantic mouth? Would this happen if their river basins had a subarctic, temperate or arid climate?

How commonly do the boundaries of major mineral provinces along a continental margin coincide with the mouth of a large river and produce contrasts like that on opposite sides of the Rio de la Plata, whose estuary separates sand of leading edge composition in Argentina from sand of trailing margin composition in Uruguay?

How carefully can we recognize subprovinces along the Andean leading edge, either on- or offshore, and relate them to onshore geology?

The effect of tectonic control on sandstone composition seems to be overwhelming, but how much relief is needed to overcome the effects of high rainfall? Could there be areas where we could sample a 'controlled experiment'?

As more samples are reported from modern beach sands and the adjacent offshore, how well will they agree? Will onshore sands have a different composition than their bordering shelf or deep seas?

Are we near the stage in regional studies of modern sands that we can deduce the sand composition of an entire continent? If so will computer modelling add a new dimension to provenance studies in the not too distant future.?

This research was funded by NSF grant EAR-80-18209. I received much help in every coastal country of South America, which will be fully acknowledged when final results are published but, until then, I thank W. R. Dickinson (University of Arizona) L. J. Suttner and A. Basu (Indiana University), K. O. Emery (Woods Hole Oceanographic Institute) and J. Barry Maynard, (University of Cincinnati) for helpful advice.

The study of particle size distributions is commonly used to investigate sedimentary processes and environments. Originally such work concentrated on typifying these distributions by their sample moments, while more recent statistical studies have proposed fitting parametric models to sample data and then using the resulting parameter estimates. We have investigated the use of log-hyperbolic and skew log-Laplace models to distinguish between beach and dune sands, with the aim of classifying the depositional environment of some mesolithic middens. We found that the former models were unsatisfactory for various numerical and physical reasons, while the latter provide a simple and robust method which is useful for the classification of sand sediments.

Barndorff-Nielsen[1,2] and Bagnold and Barndorff-Nielsen[3,4] demonstrated the statistical and geological advantages of using log-hyperbolic distributions to interpret particle size distributions. The method eliminated[1] the mathematical arbitrariness and unreliable assumption of normality associated with the use of low-order moment measures (such as, mean, median, skewness, kurtosis and developments of them[5–7], and (2) used a mathematical distribution that had been directly related to the geological processes of transportation and deposition responsible for the sediments[3,4]. Four parameters were utilized to describe the log-hyperbola: ϕ, γ, μ and δ (Fig. 1). Bagnold[1–4] suggested that the gradient ϕ was related to the significance in the particle size distribution of saltation, and that the gradient γ corresponded to the significance of coarser grains which 'creep'.

We have employed this statistical procedure to characterize the particle mass-size distributions with data obtained at $\frac{1}{2}\phi$ intervals obtained by standard procedures[8,9] from coastal beach, salting and dune environements in the Inner Hebrides, Libya and South Wales; and, in particular, to identify the depositional environments, and hence the palaeogeography, represented by shell sands of unknown origins obtained in trial pits and cores beneath late mesolithic shell middens investigated on the east coast of Oronsay, Inner Hebrides[10–13] (Fig. 2). In this latter study, samples were taken from along four transects crossing several depositional environments.

The fitting of the log-hyperbola was satisfactorily achieved both on our reworking of the published Bagnold and Barndorff-Nielsen[2,3] data and on a substantial proportion of our own data[14]. However, in four out of our 15 attempts to use this procedure no numerically stable solution was obtained. Detailed numerical investigation of these four cases revealed that the likelihood function was virtually flat with respect to the parameter δ. The physical explanation is that there are many different log-hyperbolic distributions, differing only in curvature at the peak of the distribution, which fit the data equally well. This arises because of the coarse sequence of sieves used in the collection of our data: $\frac{1}{2}\phi$ rather than the $\frac{1}{4}\phi$ intervals used in the Bagnold and Barndorff-Nielsen data. The transition from 'fine-grade fraction' to 'coarse-grade fraction' typically occurs over a range rather less than $\frac{1}{2}\phi$. Consequently, if the peak of the distribution occurs close to a mesh size of any of the sieves, then the available data provide little information on the value of this parameter δ which essentially measures the curvature of the distribution at its peak. Use of alternative numerical techniques, in particular the programs used by Barndorff-Nielsen and his colleagues[15], did not alleviate the numerical problem. Note also that the computation, using any of the numerical

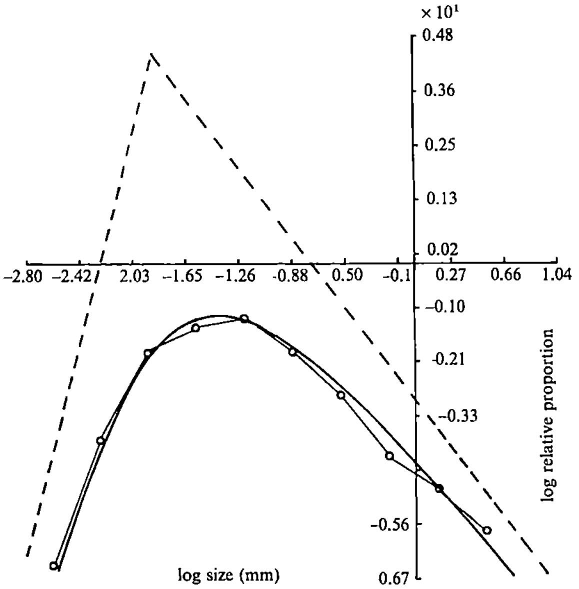

Fig. 1 Sample TUS1-6 and fitted log-hyperbolic distribution. The asymptotes to the hyperbola are shown as dashed lines. The four parameters of the distribution ϕ, γ, μ and δ are defined, respectively, as the arc-tangents of the acute angles made by the two asymptotes with the horizontal, the abscissa of the point of intersection of the asymptotes, and the difference (divided by $\sqrt{\phi\gamma}$) in ordinates of the point of intersection of the asymptotes and the maximum of the hyperbola.

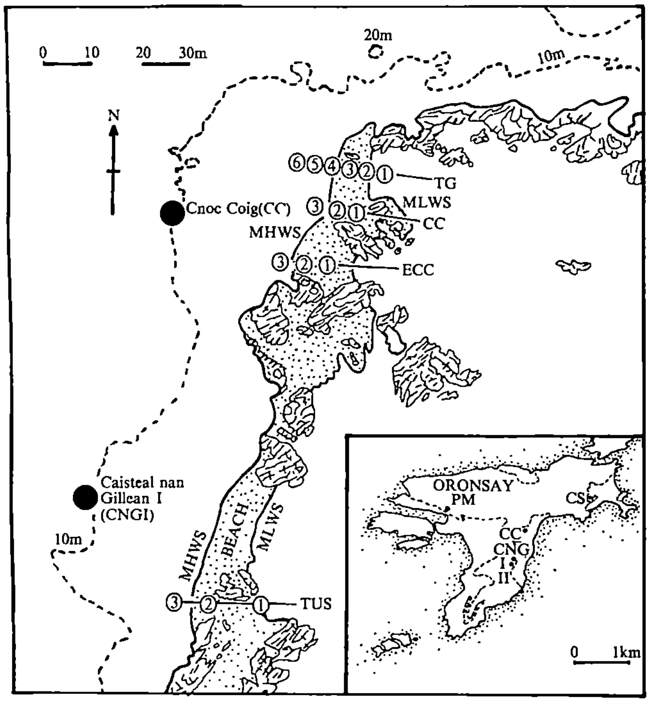

Fig. 2 Sample provenance on beach and dunes, Oronsay, Inner Hebrides and the location of the mesolithic middens and mid-Holocene shoreline (inset, after Jardine[10]). Middens: CC, Cnoc Coig; CNG I and II, Caisteal nan Gillean I and II; CS, Cnoc Sligeach; PM, Priory Midden.

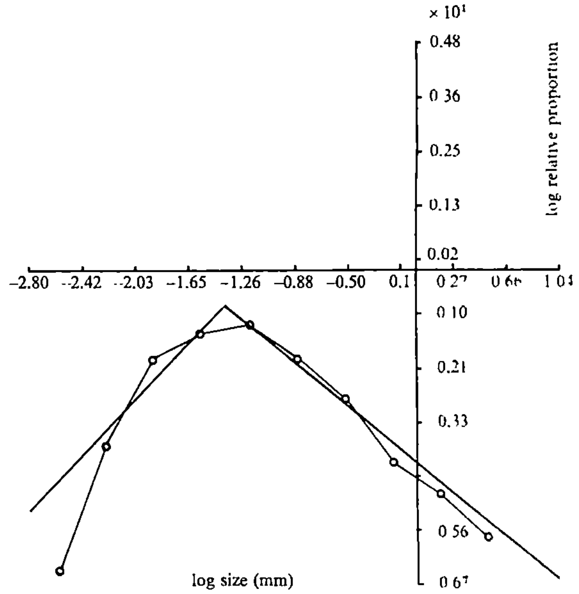

Fig. 3 Truncated skew log-Laplace distribution fitted to particle size distribution TUS1-6. The three parameters of the distribution α, β and μ are defined, respectively, as the reciprocals of the arc tangents of the acute angles made by the two lines with the horizontal axis and the abscissa of their point of intersection.

techniques, proved prohibitively expensive for application to the large number of samples involved in our study.

Another physical explanation of our difficulties is that the sand samples we dealt with were typically less 'pure' than those described by Barndorff-Nielsen[1-3]. Many of our samples were taken from less ephemeral locations, and many were indeed from archaeological sites, and might, therefore, have been subject to diagenetic and pedological changes.

To cope with these problems, we have fitted a distribution which is essentially described by two straight lines instead of a hyperbola when the mass-size distribution is plotted on log-log axes (Fig. 3). Statistically this was achieved by fitting a skew log-Laplace distribution using the program LAPSKEW.FTN[16]. This distribution was truncated to allow for the finite number of sieves and the inevitable grouping of the distribution at the upper and lower ends. The skew log-Laplace distribution can be regarded as the limiting form of the log-hyperbolic distribution obtained by letting the parameter δ tend to zero. It is conveniently parameterized by parameters, α, β and μ. Where α and β correspond to the reciprocals of ϕ and γ, and corresponds directly to the parameter μ of the log-hyperbolic distribution. LAPSKEW.FTN utilizes a modified Davidon-Fletcher-Powell algorithm[17] for determining the values of α and β for fixed μ and then a grid search for determining μ.

To illustrate the effectiveness of this approach, we have calculated and plotted values of α, β and μ for modern and mid-Holocene sand samples associated with mesolithic shell middens near the eastern shore of the Hebridean island of Oronsay (Fig. 2). Two-and three-dimensional plots of all possible combinations of the parameters have been generated, archived[9,18], and inspected. The equivalents of Friedman's[5,6] plots of standard deviation against mean; skewness against mean and skewness against variance have also been plotted as $\alpha^2+\beta^2$ against μ; α/β against μ and α/β against $\alpha^2+\beta^2$. Most of these plots present the same pattern of results and conclusions as for the case of α versus μ.

The plot of α versus μ, shown in Fig. 4*a*, reveals two clear clusters distinguished by their bay of origin. Both the mesolithic and modern samples have higher values of μ (the 'typical' grain size) at Caisteal nan Gillean (CNG) locations than at Cnoc Coig (CC) locations. Second, the values of α clearly separate modern dunes from beach sands at each location.

More detailed examination of one location—the modern environments and mesolithic sediments of CC—shown in Fig. 4*b*, indicate other important trends. Sediment samples from each transect CC, ECC and TG (Figs 2 and 4*c*) show a systematic variation in the values of α and μ from lower, via mid-beach into upper-beach and dune sands. Presumably this reflects the impact of the changing character of the transportational and depositional processes affecting the sediment.

The transects themselves are arranged in a clockwise rotation (with increasing μ and α values) from transects ECC through CC to TG (Figs 2 and 4*c*). This corresponds to, and is

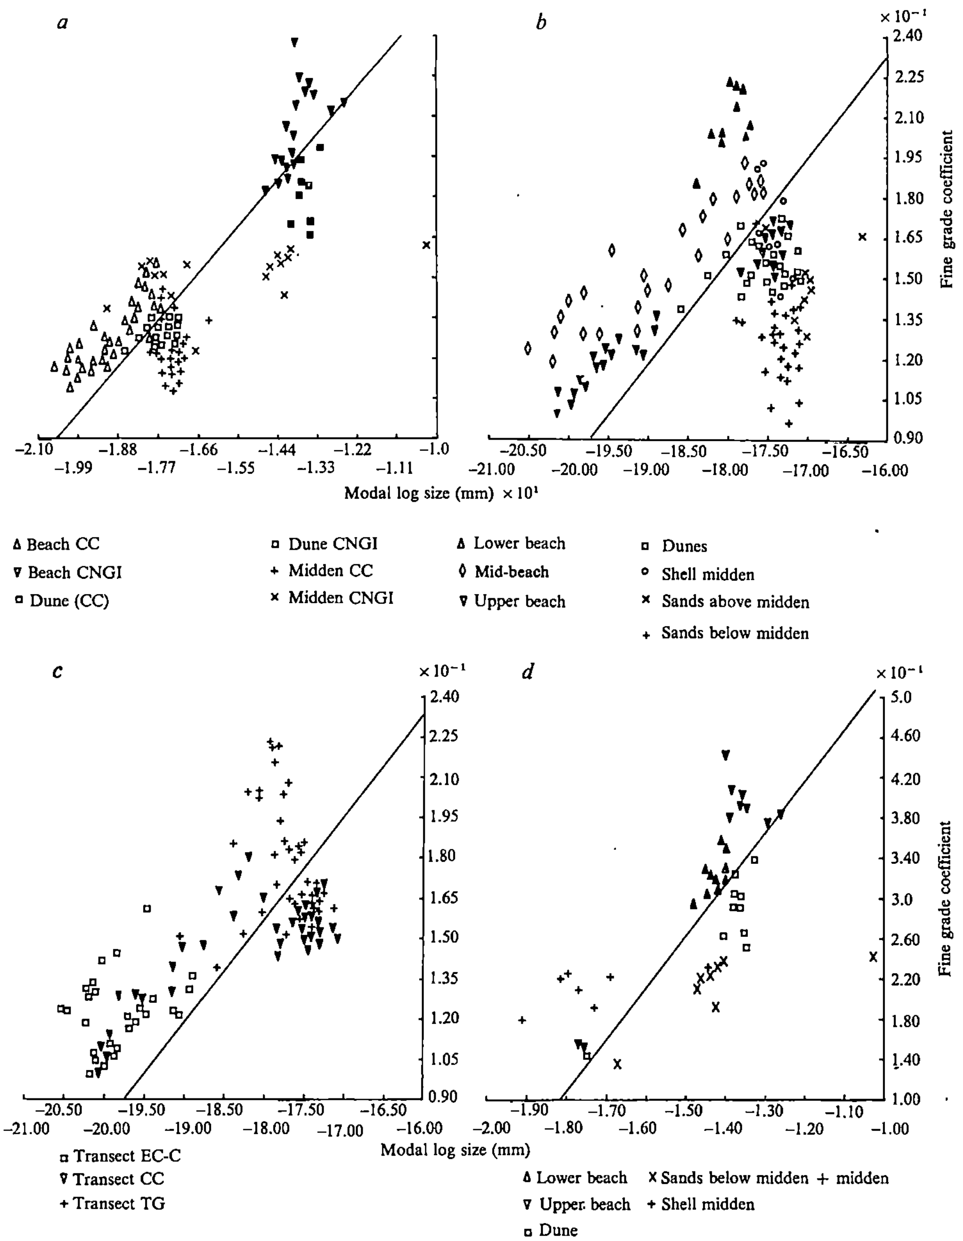

Fig. 4 Scattergrams showing the plots of modal log grain size and fine-grade coefficient of beach, dune and midden sands and the linear discriminant functions[19] separating modern beach and dune sediments at; *a*, eastern Oronsay: *b*, Cnoc Coig (showing midden samples); *c*, Cnoc Coig (distinguishing transects); *d*, Caisteal nan Gillean.

presumably the result of, a gradient from the exposed coastal locations to the relatively sheltered ECC with its protecting offshore rock bars and skerries.

In some cases, sands from the base of the dune and back of the beach are scarcely distinguishable in terms of their mass-size distribution. In practice, the components of this transitional zone are often difficult to separate in this field. The graphs of the linear discriminant functions[19] separating modern beach and dune sands (Fig. 4*b*, *c*) generally corroborate and clarify these patterns.

The sands immediately above and below the mesolithic CC shell midden are principally dune sands, but some plot in a position indicating that they might represent the actual beach/dune transitions. The sands of previously unknown origins obtained by coring beneath the midden are seen to be dune sands (Fig. 4*b*). These data have archaeological and palaeogeographical significance, as it was anticipated that the middens had accumulated on beach sand associated with the mid-Holocene sea-level maximum[10].

The sands obtained from interstices between the shells of the actual CC midden form a further distinct cluster straddling the upper beach/dune base transition. This suggests that (1) the middens were located at that position and/or (2) these particle mass-size distributions reflect sand introduced on animals, shellfish and seaweed gathered from the foreshore and/or introduced by feet and hands after harvesting activities. The sands within the CNGI shell midden (Fig. 4*d*) resemble more closely deposits found on the modern mid-beach, rather than upper beach, suggesting that the second group of explanations might be more applicable in this case.

This case study has concentrated on plots of α versus μ. In other cases, our unpublished work indicates the value of inspecting three-dimensional plots of α against β against μ. Single plots of β against μ have also provided adequate environmental discrimination in other situations. The more complex studies representing the equivalents of mean, skewness, variance and so on have not yielded notable additional information.

The data indicate that fitting skew log-Laplace distributions to particle mass-size distributions can provide a sensitive tool for the characterization and discrimination of depositional process and environments in coastal locations. The method is simple and cheap in computational terms: it can even be quickly approximated 'by hand'. It is statistically robust and has been used successfully with data obtained at $\frac{1}{2}\phi$ intervals facilitating notable savings in laboratory analyses. It retains the important assets of being directly comparable with the log-hyperbolic distribution, and consequently the slope parameters of the skew log-Laplace distribution may also be directly related to geological processes. It makes no assumptions of an underlying normal particle size distribution, but reliably describes important attributes of particle mass-size distributions.

We thank Mrs D. A. Y. Timmins for particle mass-size distribution data; Drs G. W. Jardine and P. A. Mellars for discussions; D.D.G. acknowledges the financial support for field work from the University of Sheffield research grant nos 359, 561, and 710 and W.O. acknowledges receipt of a scholarship from the Studienstiftung des deutschen Volkes.

Effect of benthic mixing on the information content of deep-sea stratigraphical signals

Paul Schiffelbein

Scripps Institution of Oceanography, La Jolla, California 92093, USA

Benthic mixing or bioturbation affects sediments in various ways, including: (1) the production of trace fossils, (2) mechanical and/or chemical alteration of the sediment, and (3) filtering or smearing stratigraphical signals[1]. Because mixing alters both the slopes and amplitudes of any recorded events, some knowledge of the process is essential for the correct interpretation of the signals. In view of recent trends towards high-resolution stratigraphy[2,3] and signal unmixing[4-6], the frequency characteristics of the benthic mixing filter must be understood to determine which types of signals can be detected after mixing. Analyses of ash and tektite profiles in deep-sea cores from various geographical regions indicate that even signals from cores having sedimentation rates as high as 7 cm kyr^{-1} will show severe attenuation of frequencies higher than 0.35 cycles kyr^{-1} (periods shorter than 2.9 kyr) resulting in loss of ability to resolve closely-spaced events. Most signals will experience much more serious high-frequency attenuation, however. The severity of high frequency loss is directly related to sedimentation rate ($R = 0.97$ for the cores examined), suggesting that this is the most important variable to take into account when considering a core for palaeoceanographic or palaeoclimatic study.

Several models have been developed to explain the filtering suffered by stratigraphical signals as they pass through the sediment mixed layer[7-9]. They express the mixing function (system impulse response) in terms of physical parameters, usually mixed-layer thickness and a diffusion coefficient, which determines the rate of transfer of material through the mixed layer. All previous workers have treated benthic mixing as a linear time-invariant system. In fact, there are several reasons why the process is expected to vary with time. Productivity, and hence sedimentation rate, varies as a function of climate. The number of benthic organisms (and hence mixing intensity), should depend on the amount of organic matter reaching the sediments[10]. Because the time-varying aspects of the mixing system are not well characterized, however, simplification is necessary.

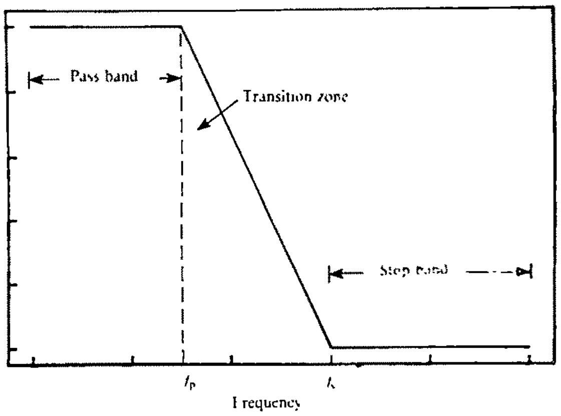

Fig. 1 Aspects of a lowpass filter. f_p and f_s are the passband and stop-band cutoff frequencies, respectively

The output and the input of a linear time-invariant system are related by the convolution integral[11]. A frequency response approach is generally used to identify such a system, which is accomplished by taking the Fourier transform of the convolution equation. The system is then represented as

$$G(\omega) = H(\omega)F(\omega)$$

where $G(\omega)$, $H(\omega)$, and $F(\omega)$ are, respectively, the Fourier transforms of the output (filtered) signal, the impulse response, and the input signal. $H(\omega)$ is called the system transfer function, as it completely describes input and output relationships[12]. Most natural processes, including benthic mixing, involve smoothing or lowpass filters, meaning that the low frequencies are passed through, while the high frequencies are attenuated. Characteristics of a typical lowpass filter are shown in Fig. 1. The passband extends from zero frequency to the cutoff frequency f_p. The stopband extends from the cutoff frequency f_s to the Nyquist frequency. The region between f_p and f_s is the transition region.

Many volcanic ash and tektite profiles have been measured in deep-sea sediment cores from a broad range of geographical areas[13-17]. These profiles represent system impulse response functions due to the instantaneous nature of the inputs. Officer and Lynch[18] compiled 16 of these profiles, which were then fit to theoretical mixing profiles using the model of Guinasso and Schink[9]. These profiles were thus parameterized in terms of mixed layer thickness d and diffusion coefficient D. These parameters and a truncated series solution of the mixing equation[18] can be used to regenerate the mixing profiles. The regenerated curves offer an advantage over the measured profiles when investigating the mixing transfer function in that counting noise and mixing heterogeneity are effectively smoothed out. The power spectrum of each mixing function is calculated to determine the frequency characteristics of the transfer functions.

In practice, the passband cutoff frequency is usually defined as the halfpower point[19], that is the frequency at which one half of the input signal power is attenuated (−3 dB). As an example, the mixing function from core RC17-126, is shown in Fig. 2. The halfpower point (−3 dB) is at a frequency 0.14 cycles kyr (f_p). Frequency response decreases ('rolls off') at roughly 10 dB per octave (an octave refers to a doubling of frequency). The benthic mixing filter analyses for the 16 profiles are summarized in Table 1, and −10 dB (signal attenuated one order of magnitude) points are provided to give some idea of filter roll-off. Most stratigraphical signals (such as, oxygen isotopes) do not have a signal-to-noise ratio >10 dB (ref. 20), so these numbers also give some idea of an absolute attenuation frequency (f_s).

The f_p values shed some light on the affects of benthic mixing on stratigraphical signals, as they span well over an order of magnitude. Even in the cases of minimal signal attenuation, all wavelengths $\leq$3,000 yr are substantially attenuated. This level of filtering will smooth out rapid transitions or transients (such as glacial–interglacial transitions), and obscure the relationships of closely-spaced events. This is true even when sedimentation rates are high (for example, 7 cm kyr^{-1} in cores V19-28 and V19-29). Most deep-sea cores used for palaeoceanographic or palaeoclimatic analysis tend to have sedimentation rates of the order of 1–2 cm kyr^{-1}. Mixing filters in Table 1 corresponding to cores of this type have a passband cutoff at a period of roughly 10,000–20,000 yr. While filters of this severity would not obscure Milankovitch or orbital frequencies (20 kyr–100 + kyr), they will lead to some reduction in the amplitudes of these spectral peaks[21] and will certainly make the results of any high-resolution study (sampling every 500–1,000 yr) questionable, unless there were some sort of signal restoration (deconvolution).

A relationship between sedimentation rate and mixed layer thickness has been observed in equatorial Pacific box cores[22], suggesting a link between the amount of benthic mixing activity, primary productivity of the overlying surface waters, and the consequent flux in surface sediments. A strong correlation between sedimentation rate and mixed layer thickness would not be expected in areas with terrigenous influx, or in areas not so strongly controlled by biogenous sediment production. Using radiotracers in cores from diverse geographical areas, DeMaster and Cochran[23] found no systematic relationship between depth of mixing or mixing rate and sedimentation rate. A similar statement can be made for the cores listed in Table 1.

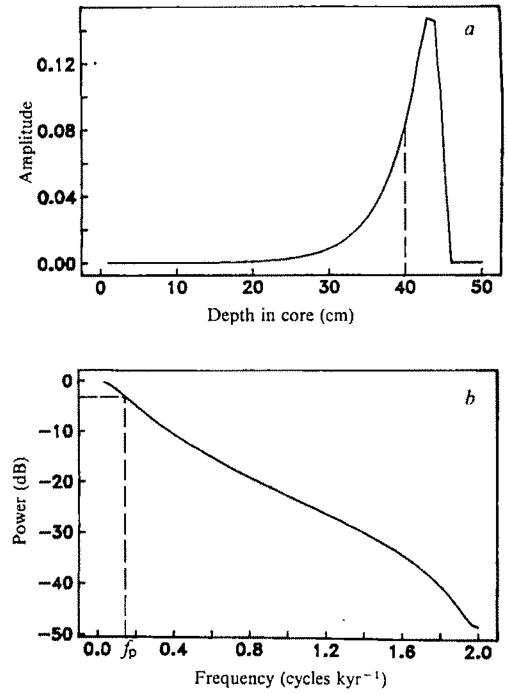

Fig. 2 Mixing function from core RC17-126. *a*, The impulse-response function, or time-domain representation of the filter, as easured from volcanic ash concentrations down core. Tracer impact depth was set arbitrarily at 40 cm (vertical dashed line). Vertical scale is in arbitrary units, and reflects unit-area normalization of the curve. *b*, The frequency-domain representation of the filter. Passband cut-off frequency (f_p) is taken to be the half-power (−3 dB) point.

The values in Table 1 suggest that sedimentation rate is the variable with the most direct influence of f_p, and hence the information contained in a deep-sea core. A linear regression of f_p values against sedimentation rates for the 16 entries in Table 1 yielded the equation $f_p = 0.05\, v$, with a correlation coefficient of 0.97. Rewriting in terms of period, and rearranging, yields $v(\text{cm kyr}^{-1}) = 20.0/\text{period (kyr)}$. This equation, based on the half-power points from the benthic mixing filters examined, can be used to find the appropriate minimum sedimentation rate required to ensure recovery of a given signal period (or frequency). To recover a signal of period 4 kyr, for example, requires a minimum sedimentation rate of about 5 cm kyr^{-1}. Many 'high-resolution' studies hope for better resolution than this, yet rarely use cores having such high sedimentation rates. Even if the −10 dB points are used to construct an equation ($f_{-10\,\text{dB}} = 0.14\, v - 0.01$; $R = 0.97$), in the hope that the 10 dB of lost gain can be restored by deconvolution, a sedimentation rate of 2 cm kyr^{-1} still yields a resolution of only ~4 kyr. Resolving a period of 1 kyr requires a core having a sedimentation rate of roughly 7 cm kyr^{-1}. That benthic mixing places severe restrictions on the time resolution of data recovered from deep-sea cores has long been appreciated[24], but the quantitative effects of mixing on signal recovery have received little attention. Hence, sampling of deep-sea cores often proceeds on arbitrary or intuitive grounds, usually with an optimistic idea of stratigraphical resolution. Sedimentiation rate is seen to be the primary control and limiting factor on signal resolution in deep-sea cores. Unless there is some way of increasing the signal-to-noise ratio (such as signal stacking), and/or a core of extremely high sedimentation rate is used, there is little to be gained from

Table 1 Benthic mixing filter characteristics

Pre-Columbian age for North American *Corispermum* L. (Chenopodiaceae) confirmed by accelerator radiocarbon dating

J. L. Betancourt*, A. Long*, D. J. Donahue†, A. J. T. Jull† & T. H. Zabel†

* Department of Geosciences and † NSF Accelerator Facility for Radioisotope Analysis, University of Arizona, Tucson, Arizona 85721, USA

Criteria for recognizing alien (historically introduced) plants in continental floras are largely inferential, involving range disjunctions, absence in the first botanical records for a region, pioneer status in secondary successions ('weedy habit'), and, to a lesser extent, the fossil record. Decisions on whether a species is native or introduced commonly appear in local and regional floras. In a few cases, the plant's occurrence in the fossil record has reversed its presumed alien status[1]. Ironically, the appearance of assumed introduced species in prehistoric contexts could also be taken as an index of modern contamination due to stratigraphical mixing. We now present conclusive evidence for the prehistoric occurrence of *Corispermum* L. (Chenopodiaceae), a herbaceous annual growing on sandy soils throughout western North America, where it was previously reported as adventive from Eurasia. The use of tandem accelerator mass spectrometry (TAMS) for direct radiocarbon measurement of seeds eliminates problems with stratigraphical mixing and using this method we verify a pre-Columbian age for *Corispermum*.

The genus *Corispermum* is best represented in the semi-deserts of Eurasia. *Corispermum hyssopifolium* L. and *C. nitidum* Kit ex. Schult. are the two Eurasian species that today occur in North America, thought to have been introduced at the time of European settlement. *Corispermum hyssopifolium* has been regarded as endemic to southern Russia and adventive or partly indigenous in central and southern Europe. It is the most widely distributed species in North America. *Corispermum hyssopifolium* and *C. nitidum* are the only species reported in modern floras of Alaska and the Yukon, but at least five species with no recognized Old World synonyms have been described from type specimens in the Rocky Mountain states, US. Three of these species, *C. villosum* Rydb., *C. emarginatum* Rydb., and *C. marginale* Rydb., were described at the turn of the century by Rydberg[2]. His reputation for taxonomic splitting[3] may have influenced some workers in synonymizing his and other North American species with *C. hyssopifolium* or *C. nitidum*[4,5]. Further confusion results from at least one worker assigning alien status to one of the North American species (*C. villosum*) which Rydberg described[6].

The suggestion in many North American floras that *C. hyssopifolium* arrived only recently seems peculiar in view of early historical records from what was then remote wilderness. John Richardson found it on the shores of the Great Slave Lake, western Canada in 1821[7]. In the 1870s, Joseph T. Rothrock collected *C. hyssopifolium* in Colorado[8]. Hence, it is not surprising that an extensive record for pre-Columbian *Corispermum* has emerged in areas where early botanists first collected it.

Table 1 summarizes select localities and direct or associated conventional dates for *Corispermum* seeds in fossil contexts from northwest Canada, Alaska, and the Colorado Plateaus in the United States. The seeds are very distinctive and may resemble ticks to the unaccustomed eye (*Cori* = bug, Greek; *spermum* = seed, Latin). Seeds are oval in outline, flat and slightly concave-convex, with a persistent encircling wing. The base of the wing is emarginate or rounded, and the apical end bears two minute, toothlike style bases[9] (Fig. 1). Average seed dimensions are 5×4×0.5 mm. An attempt to distinguish species of *Corispermum* based on seed size and morphology from modern voucher specimens yielded erratic results, though in some cases fossil and modern seeds of a particular species are close facsimiles (Fig. 1*c* and *d*).

Fossil contexts for *Corispermum* seeds include alluvium[10,11], cave fill[12,13], human and herbivore coprolites[12,14], archaeological sites[12,13,15–17], and fossil packrat (*Neotoma*) middens[18–20]. Direct evidence for *Corispermum*'s role in the prehistoric human diet include its presence in human coprolites, as parched seeds in hearths, and some 80 cm^3 of seeds cached in a Mimbres pottery jar from Swartz Ruin, New Mexico. Associated ages in the various contexts range from >38,000 yr BP in the Yukon to <1,000 yr BP in archaeological sites on the Colorado Plateaus. Four of the localities contained sufficient seeds from a single context to allow direct radiocarbon measurements by TAMS. The mass of the seeds in these samples ranged from 5 to 17 mg per sample (8–15 seeds per sample). We followed routine radiocarbon dating procedures, by pretreating each sample with 1 M HCl, then 2% NaOH, again with HCl, and finally washing it thoroughly with distilled water. Target preparation involved first, pyrolysis *in vacuo*, then heating the carbonized material with powdered iron under argon to form a spheroid of cast iron. Details of target preparation and radiocarbon measurement procedures are given elsewhere[21]. All four of the direct dates generally agree with the associated ages of the samples. The oldest direct dates for *Corispermum* are 9,970 ± 460 yr BP for the Canadian and Alaskan sites and 14,500 ± 600 yr BP for the Colorado Plateaus.

A pre-Columbian age for *Corispermum* and the present discontinuity in its range between Siberia and Alaska raise questions about points of origin, dispersal routes, arrival times, and subsequent evolution in North America. In the late Cenozoic, the most reasonable dispersal route would have been from northeastern Siberia across the Bering Land Bridge to Alaska. The presence of *Corispermum* seeds in herbivore dung, tentatively assigned to *Mammuthus*, from Cowboy Cave[12] and Bechan Cave[14] in southeastern Utah, suggests one mode of dispersal. In the Yukon, associated dates from alluvium containing *Corispermum* seeds indicate an arrival time >38,000 yr BP. The best candidates for the Yukon and Alaskan records are probably *C. hyssopifolium* and *C. nitidum*, the only species presently in the region and the ones that were assumed to be recent European introductions. Beringian phytogeographers, taxonomists, and palaeoecologists disagree about the timing for intermingling of

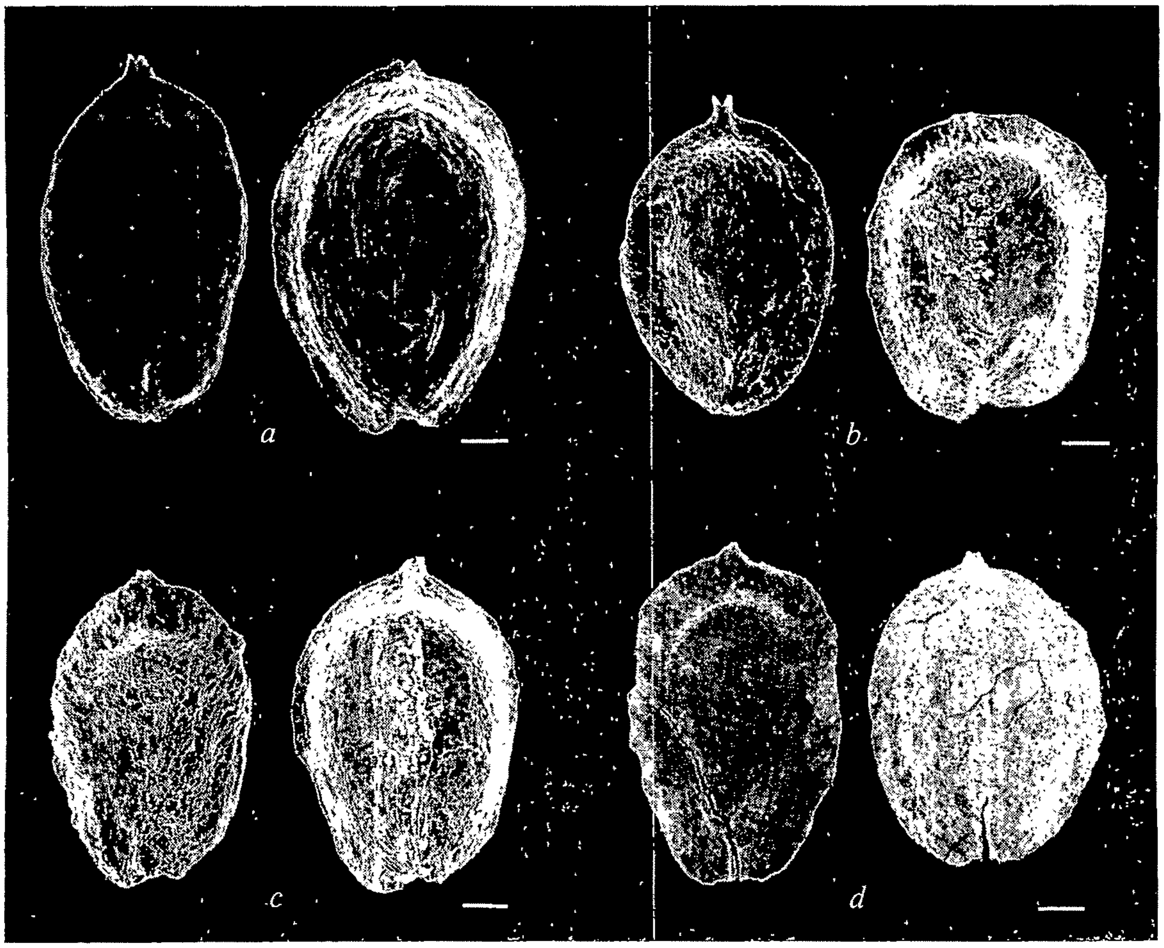

Fig. 1 Scanning electron micrographs of modern (*a–c*) and fossil (*d*) *Corispermum* seeds. Convex surfaces are shown on the left and concave ones on the right for each pair of seeds. Scale bars, 500 μm. *a*, Modern seeds of *C. hyssopifolium*; *b*, modern seeds of *C. nitidum*; *c*, modern seeds of *C. villosum*; *d*, fossil seeds from *Neotoma* midden in northwestern New Mexico. Seeds from this midden were directly dated by accelerator mass spectrometry to 3,880±240 yr BP. Note the similarity between *d* and *c*, a North American species with no Eurasian synonym.

Table 1 Select fossil localities for *Corispermum* in North America

Area	Site	Lat.	Long.	Context	Associated age (yr BP)	Direct age (yr BP)	Ref. for associated age
Yukon Territory, Canada	Bell Basin, Upper Porcupine River	66°56.7′ N	137°42.5′ W	Alluvium	>38,000 (GSC-2274)	None	10
Northwest Territory, Canada	Great Bear River	64°56.5′ N	125°29.75′ W	Alluvium	10,600±260 (GSC-2328)	9,970±460 (A-3748)	10
Arctic Coastal Plain, Alaska, USA	Ikpikpuk River	69°43.0′ N	154°53.0′ W	Alluvium	9,670±130 (I-11,073) 9,430±160 (I-13,174)	9,100±350 (A-3900)	11
Northern Arizona, USA	Grand Canyon, Shinumo no. 1	36°00.0′ N	112°29.0′ W	*Neotoma* midden	13,660±160 (A-1321) 12,070±600 (A-1444)	14,500±600 (A-3539)	18

Southeastern Utah, USA	Bechan Cave	37°40.0′ N	110°45.0′ W	Herbivore coprolites	>11,670±300 (A-3212)	None	14

Associated ages are based on conventional radiocarbon dating of other organic material in same context as *Corispermum*. Direct ages were obtained by TAMS analyses of *Corispermum* seeds. All dates are in radiocarbon years before present. Radiocarbon laboratory numbers are enclosed in parentheses.

eastern and western steppe floras[22]. Because *Corispermum* may have undergone adaptive radiation and speciation after its arrival, perhaps within the past 2 Myr, its taxonomic and evolutionary status in North America should be critically re-examined.

Finally, plants of questionable origin are often herbaceous and thus contribute little biomass in depositional environments. More often than not, there is insufficient material (<1 g of carbon) for conventional β-counting methods. Hence, we anticipate application of direct radiocarbon determinations by TAMS, useful for samples of just a few milligrams, as a routine investigative tool to resolve questions about alien or native status for other problematical plants in the fossil record.

Seabird colony distributions suggest competition for food supplies during the breeding season

R. W. Furness

T. R. Birkhead

Department of Zoology, University of Sheffield,
Sheffield S10 2TN, UK

There is long-standing disagreement over the way in which seabird populations are regulated[1]. They may be regulated by density-dependent mortality during winter as a consequence of food shortage[2–4], shortage of nest sites[5–7], social factors[8], or not regulated at all[9]. Ashmole[10,11] argued that for tropical seabirds, density-dependent mortality of adults outside the breeding season is most unlikely because intraspecific competition for food close to the colony would result in prey depletion, causing adults to travel increasing distances for food as colony size increased. Breeding numbers could be regulated through a density-dependent reduction in reproductive output resulting from reduced rates of provisioning of chicks. This mechanism may not apply to seabird colonies in higher latitudes, however, because seasonal production might provide superabundant food supplies during the breeding season. Recent studies of the quantity of food consumed by breeding seabirds[12–15] suggest that prey depletion also occurs in temperate regions and invites a critical test of Ashmole's hypothesis. We present here an analysis of interactions between spatial distribution and size of seabird breeding colonies and provide support for Ashmole's suggestion that seabird numbers may be limited by intraspecific competition for food around colonies during the breeding season.

We tested the idea of prey depeletion by considering spatial distribution and sizes of seabird colonies, as a direct demonstration would require an expensive marine sampling programme. If Ashmole's model is correct, then in an area of uniform mean productivity, colony size should be strongly and negatively related to the number of competitors from other colonies which are feeding within the foraging range used by members of the colony.* Such a relationship would not be predicted by any of the other models. Indeed, if numbers were limited by nest sites, one might expect large colonies to be spatially aggregated (the opposite trend), as geologically similar islands will tend to occur together. Further, there is no reason to expect that any pattern in the distribution of islands should affect all four data sets.

Table 1 Correlations between seabird colony size and numbers at other colonies within a given range

Species	Range (km)	Mean no. of colonies within range	Correlation	*P*
Gannet	100	0.8	−0.92	<0.001
(12 colonies)	150	0.8	−0.92	<0.001
	200	1.0	−0.47	NS
	300	1.8	−0.51	NS
Puffin	50	0.7	−0.56	<0.05
(15 colonies)	100	2.5	−0.81	<0.001
	150	4.9	−0.88	<0.001
	200	6.6	−0.74	<0.001
	250	9.0	−0.58	<0.05
Shag	20	2.0	−0.45	<0.05
(27 colonies)	30	3.5	−0.54	<0.01
	40	4.9	−0.48	<0.05
	50	6.4	−0.58	<0.01
	60	7.2	−0.66	<0.001
	70	8.1	−0.32	NS
	80	9.3	−0.24	NS
Kittiwake	20	1.5	−0.55	<0.01
(22 colonies)	30	3.3	−0.49	<.05
	40	4.9	−0.67	<0.001
	60	8.8	−0.36	NS
	80	11.7	−0.32	NS
	100	14.5	−0.08	NS

Competition for food is a function of the density of conspecifics, which is proportional to the square root of the number of birds, so we have used square root transformations of numbers. NS, not significant.

Reliable census data for all colonies of a species in a restricted area of relatively uniform oceanography and productivity are scarce. We have analysed four sets; for gannets (*Sula bassana* (L.)), puffins (*Fratercula arctica* (L.)), shags (*Phalacrocorax aristotelis* (L.)) and kittiwakes (*Rissa tridactyla* (L.)) in parts of Britain and Ireland. To restrict our analysis to areas of relatively uniform oceanography, we considered the smallest possible

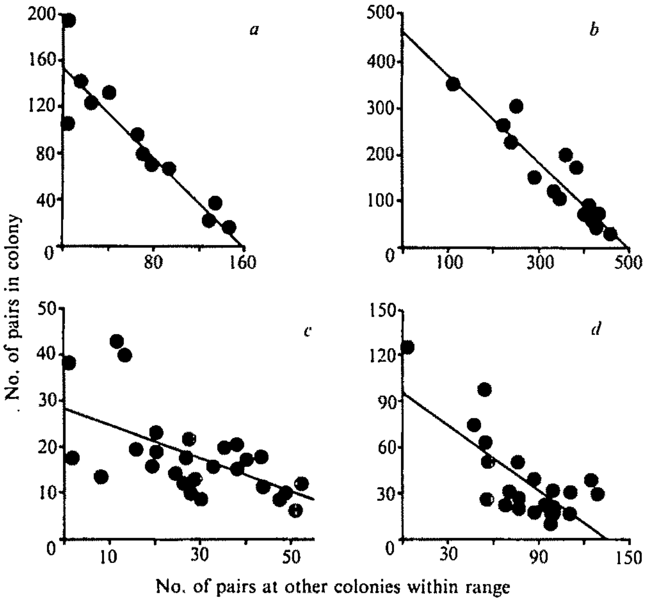

Fig. 1 Relationships between sizes of colonies and numbers at other colonies within a specific shortest sea distance for gannets, 100 km (*a*); puffins, 150 km (*b*); shags, 30 km (*c*); and kittiwakes, 40 km (*d*).

geographical area compatible with the need for an adequate sample size. For gannets, we used the most recent census data[16-18] for each colony founded before 1960 in Scotland, Ireland and Wales. We did not include colonies in England, France or the Faeroes; the first two are in an oceanographically different water mass[19], and the last is the only colony which is still heavily exploited by man as well as being distant from the colonies under consideration. We also ignored the four colonies founded in the 1970s because these are too young to have increased beyond a very small number of pairs and so are likely to be well below their optimum numbers. There is a high negative correlation for ranges of 100 km and 150 km. For greater ranges the correlation tends towards zero (Table 1). The highest correlation occurs where most colonies have only one other colony within their range and this leads to statistical difficulties of interpretation because points are not independent. This problem was overcome by carrying out 999 randomizations of colony sizes. None resulted in a correlation greater than that observed.

For puffins we took census data directly[20] and considered all colonies of over 1,000 pairs in Scotland north of 57°30′N, a total of 15 colonies holding over 97% of the Scottish puffin population[20]. There is a high negative correlation for ranges of 100-200 km (Table 1).

For shags we included all colonies of 40 pairs or more in Orkney and Shetland[21] (>95% of the Orkney and Shetland total[21]) and for kittiwakes we examined 1981 census data for Shetland[22]. Patterns for these species (Table 1) are similar to those already described. Species with shorter foraging ranges are more likely to be influenced by local variations in marine productivity; our assumption that mean productivity is uniform is a weakness of this test of Ashmole's hypothesis, but the fact that strong correlations do exist in spite of this strengthens our confidence in the result.

For puffins, and to a lesser extent for shags and kittiwakes, correlations over the shortest ranges are poorer than those over slightly greater ranges, partly due to the small number of colonies within the shortest range (Table 1). The tendency also arises because for short ranges the size of a colony may be influenced by the presence of a large colony just outside the range considered, whereas for large ranges the additional influence of a colony outside the range is very much less.

The strong negative relationships imply that seabird colony sizes are strongly influenced by numbers of conspecifics competing for food near to the colony. This interpretation is strengthened by the fact that the relationships are most pronounced over distances which match the foraging range of the species. Normal maximum foraging ranges of shags are 10-30 km[23,24], for kittiwakes 40-60 km[24], for puffins 10-150 km[24,25] and for gannets 100-150 km[16], while the closest relationships occur respectively over ranges of 30-60 km, 20-40 km, 100-200 km and 100-150 km (Fig. 1).

Numbers of nest sites may restrict the size of some particular colonies, but the distribution and size of other colonies usually compensates for this to raise the overall species' density to that limit set by food availability during the breeding season. The mechanism for the regulation of colony size is presumably through variations in recruitment in relation to colony breeding performance, possibly resulting from the tendency of young to recruit into their natal colony; however, recruitment processes in seabirds are poorly understood.

Excitatory amino acids directly depolarize rat brain astrocytes in primary culture

C. L. Bowman* & H. K. Kimelberg*†

Division of Neurosurgery* and Departments of Anatomy† and Biochemistry†, Albany Medical College, Albany,
New York 12208, USA

L-glutamic acid (L-Glu) and L-aspartic acid (L-Asp) are considered to be major excitatory amino acid transmitters, causing depolarization and excitation of neurones in the mammalian central nervous system (CNS)[1,2]. These responses have been thought to be an exclusively neuronal property as the excitatory amino acids either did not affect the potential of electrophysiologically unresponsive glial cells[3,4], or when an effect was seen, it was attributed to changes in external [K$^+$] (refs 5, 6). Here we report that L-Glu directly depolarizes immunocytochemically-identified astrocytes in primary culture. L- or D-Asp and kainic acid (KA) also depolarized these cells while none or minimal changes in the resting membrane potentials were found in response to *N*-methyl-D-aspartate, D-glutamate, taurine, L-glutamine or to the inhibitory amino acids γ-aminobutyric acid (GABA) and glycine. We conclude that the membrane potential of astrocytes can no longer be thought of as being responsive only to K$^+$ and that the electrophysiological effects of excitatory amino acids *in situ* may not be exclusively a neuronal property.

When astrocytes were bathed in a solution of L-Glu (10^{-4} M), rapid depolarization was detected, followed by a slow repolariz-

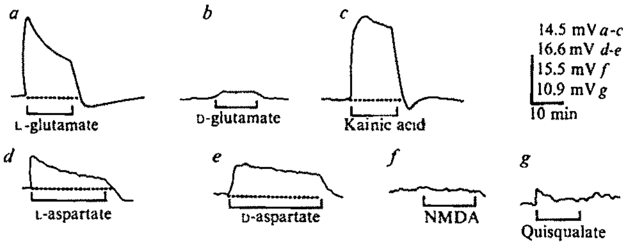

Fig. 1 *a*–*g*, Membrane potential responses of cultured astrocytes to excitatory amino acids and other agonists. NMDA, *N*-methyl-D-aspartate. Final concentrations of all additions were 10^{-4} M and perfused for the times marked on the figures. Dashed lines indicate pre-addition baseline. The temperature ranged between 35–37 °C and was maintained by heating the room. Membrane potentials of the cells shown before addition of the amino acids were *a*, −85; *b*, −87; *c*, −78; *d*, −56; *e*, −70; *f*, −86; *g*, −64 mV. Recordings shown in *a*–*g* are from separate cells. All cells responded to L-Glu (10^{-4} M).

Methods: Astrocytes were grown as primary cultures from neonatal rat brains as described previously[10,11,15,28], with the exception that the brain tissue was dissociated using a neutral protease (Dispase II, Boehringer-Mannheim)[29]. These cultures show ≥90% staining of the cells[10,28,29] for the astrocyte marker GFAP[8,9]. Membrane potentials were measured using standard electrophysiological recording techniques as previously described[11,15]. Microelectrodes were filled with 0.5 M K_2SO_4, buffered with 5 mM HEPES, *p*H 7.2 instead of KCl-filled electrodes as we have found that the use of K_2SO_4-filled microelectrodes allowed us to record from the cells for longer periods of time. The bathing medium consisted of 122 mM NaCl, 2.8 mM KCl, 1.2 mM KH_2PO_4, 1.3 mM $CaCl_2$, 0.4 mM $MgSO_4$, 10 mM D(+) glucose and 25 mM HEPES adjusted to *p*H 7.4 with NaOH (total [Na^+] was 140 mM and total [K^+] was 4.5 mM). The electrophysiological recordings were made under conditions of continuous perfusion using a Nikon Diaphot inverted microscope equipped with Hoffman modulation contrast optics as previously described[11]. The bathing medium and stock solutions (10 mM) of the amino acids were made in glass distilled water 1 to 2 h before use. L-glutamic acid hydrochloride was obtained from Sigma Chemical Co., St Louis, Missouri.

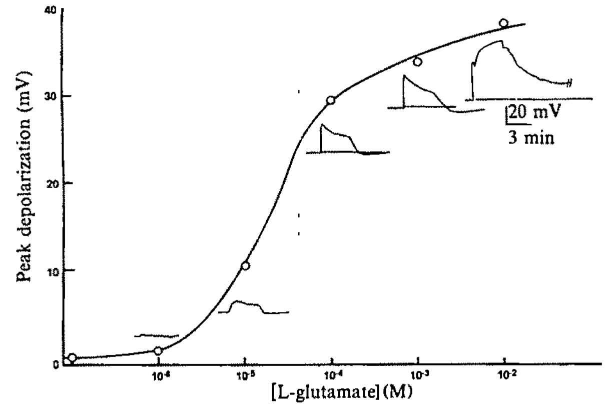

Fig. 2 Depolarizing responses to varying concentrations of L-glutamate. Initial peak depolarizations are plotted. Representative examples of the responses obtained at different concentrations are shown. Records are from a single cell. Other conditions are as in Fig. 1.

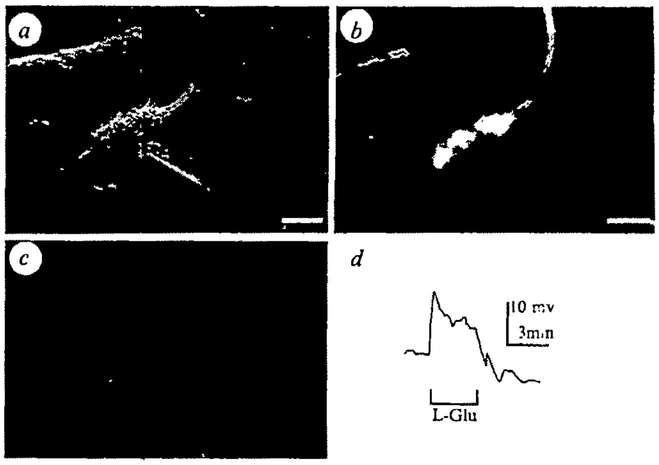

Fig. 3 Cells that are depolarized by L-Glu contain glial fibrillary acidic protein. *a*, Impaled cell viewed through Hoffman modulation contrast. Electrode is visible impaling cell from right-hand corner *b*, Same cell after fixation and staining for GFAP, viewed through fluorescent optics. Filamentous staining is clearly visible in processes. Bar in *a* and *b* represents 20 μM. *c*, Fluorescent micrograph of another coverslip where the primary antibody was absorbed with bovine GFAP. *d*, L-Glu (10^{-4} M) induced depolarization from same cell as in *a* and *b*. Resting membrane potential was −42 mV

Methods: Cells were recorded from as described in Fig. 1. The impaled cells were then photographed, an area on the underside of the coverslip was marked with a diamond object marker (Leitz) and photographs of the mark were made[11]. This procedure allowed us to identify the impaled cell after staining for GFAP After all recordings, photographs and marks were made the coverslip was removed and the cells stained for GFAP as described previously[11,28]. A monoclonal antibody (Amersham) directed against GFAP was used as the primary antibody. It was specified as being positive only for glial cells in human and rat brain and did not react with a variety of other tissues. The second antibody was goat anti-mouse IgG conjugated with fluorescein. Using a Nikon Labophot microscope the areas containing the impaled cells were identified by means of the marks previously made with the diamond object marker and the impaled cells identified using the photographs. Fluorescent micrographs were then taken of these cells. Controls were established by omitting the primary antibody, or by absorbing the primary antibody with bovine GFAP and were all negative (*c*). Also, neuronal primary cultures from rat hippocampus[30] did not stain using this monoclonal antibody.

ation in the continued presence of L-Glu (Fig. 1*a*). The removal of L-Glu resulted in a rapid repolarization which was followed by a transient hyperpolarization and then a slower recovery to the baseline membrane potential (Fig. 1*a*). The mean magnitudes of the L-Glu (10^{-4} M) induced depolarization, repolarization and hyperpolarization were 19±7 mV (mean ±s.d., 48 cells), 8±4 mV (48 cells) and 4±3 mV (46 cells) respectively. The resting membrane potentials were −71±10 mV (48 cells). We have observed an L-Glu induced depolarization in all cells (48 in total) tested from six different primary cell cultures. The age of these cultures ranged from 21 to 36 days. Perfusion of D-Glu (10^{-4} M, 4 cells) resulted in only a small depolarization (Fig. 1*b*) showing that the L-Glu-induced depolarization was stereospecific. Bathing the cells with KA (10^{-4} M, 7 cells), L-Asp (10^{-4} M, 3 cells) or D-Asp (10^{-4} M, 2 cells) also resulted in a depolarization of the resting membrane potential (Fig. 1*c*, *d* and *e*). The magnitude of the KA-induced depolarization was usually equivalent to that seen for L-Glu whereas the effect of L- or D-Asp was generally less. *N*-methyl-D-aspartate (NMDA) (10^{-4} M, 3 cells) and quisqualate (QA) (10^{-4} M, 5 cells) were without effect, or only minimally effective (≤4 mV) (Figs. 1*f*, *g*). The inhibitory amino acids, glycine (10^{-4} M, 10 cells), GABA (10^{-4} M, 4 cells), taurine (10^{-4} M, 3 cells) and the L-glutamate metabolite L-glutamine (10^{-4} M, 3 cells) had no effect on the membrane potentials (data not shown). The lack of effect of GABA may not be surprising as only a non-neuronal low affinity [^{3}H]-flunitrazepam binding site has been found in cultured glial cell membranes[7].

Figure 2 shows the responses from a single cell and demonstrates that the 50% effective concentration (EC_{50}) of the L-Glu-induced depolarization was approximately 50 μM. The shape of the response was altered at the highest concentration tested (10^{-2} M), with the appearance of a second slower depolarization that overcame the normal pattern of partial repolarization in the presence of L-Glu and a slower repolarization after removal of L-Glu (compare responses to 10^{-2} M L-Glu with 10^{-4} M L-Glu in Fig. 2). Similar results were obtained from another cell.

Since at least 90% of the cells in our cultures stain for glial fibrillary acidic protein (GFAP), and intermediate filament

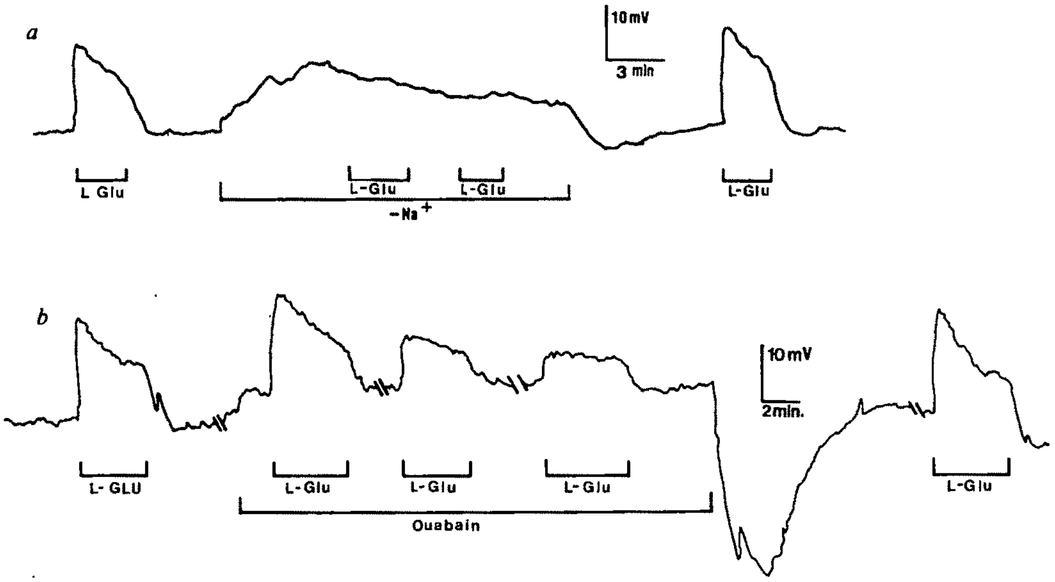

Fig. 4 The L-Glu induced depolarization requires external Na$^+$. [L-Glu] was 10^{-4} M. *a*, L-Glu response in normal Na$^+$ medium (see Fig. 1) and in the absence of Na$^+$ ($-$Na$^+$). In the latter case, Na$^+$ was replaced mole for mole by choline. In the absence of impalement removal of Na$^+$ either did not alter the electrode potential or at most changed it by 1-2 mV. Resting membrane potential of this cell was −72 mV. *b*, Effect of 1 mM ouabain on the L-Glu induced depolarization. The breaks in the tracings represent approximately 2 min. Resting membrane potential for this cells was −70 mV.

protein considered specific for astrocytes[8,9], and since the cells have essentially linear current-voltage characteristics[10,11], we considered it unlikely that all our electrophysiological recordings were from any contaminating neuronal cells. However, because it is well-established that L-Glu depolarizes and excites neurones and as previous investigators had found no evidence for a direct electrophysiological effect of L-Glu on mammalian glial cells *in vivo*[3] or *in vitro*[4-6], we determined whether the cells in our cultures depolarized by L-Glu were astrocytes by post-staining such cells for GFAP. Figure 3 shows a cell depolarized by L-Glu and showing positive staining for GFAP. Similar results were found in 2 other cells. Therefore, we conclude that astrocytes in our primary cultures are directly depolarized by L-Glu.

Astrocytes in primary culture show Na$^+$-dependent high affinity uptake of L-Glu[12,13]. Thus, an electrogenic uptake of L-Glu with Na$^+$ might be partially or wholly responsible for the depolarization. Alternatively, the L-Glu induced response could be the result of an increased Na$^+$ conductance. To test these alternatives we investigated the effect of removing external Na$^+$ on the L-glu-induced response. Removal of Na$^+$ (replaced with choline) alone resulted in a depolarization, initially of 14 mV which then repolarized by 6 mV (see Fig. 4*a*). We have previously reported [11,14] a depolarizing response to omission of external Na$^+$ in primary astrocyte cultures which we suggested could be partly due to inhibition of an electrogenic Na$^+$/K$^+$ pump and/or a secondary consequence of other effects of no external Na$^+$, such as modification of intracellular *p*H due to inhibition of Na$^+$/H$^+$ exchange. In the absence of external Na$^+$, perfusion of L-Glu had no further effect on the resting membrane potential (Fig. 4*a*). Subsequent addition of Na$^+$ and re-perfusion of L-Glu resulted in a normal L-Glu-induced depolarization identical to that seen before removal of external Na$^+$ (Fig. 4*a*). Similar results were obtained when Na$^+$ was replaced with arginine (data not shown). These results show that external Na$^+$ is required for the L-Glu induced depolarization. Because we found that the L-Glu-induced depolarization is not affected by tetrodotoxin (10^{-6} M) (data not shown) an involvement of veratridine-induced Na$^+$ channels that we have recently observed in these cells[11], is unlikely.

Although the present data do not allow us to distinguish between an electrogenic Na$^+$-dependent L-Glu uptake mechanism, or activation of an L-Glu receptor resulting in a depolarizing conductance change to Na$^+$, both mechanisms should involve an inward movement of Na$^+$. Thus, the repolarization in the continued presence of L-Glu could involve activation of an electrogenic Na$^+$/K$^+$ ATPase due to an increase in $[\mathrm{Na}^+]_i$. To test for this possibility, we studied the effect of ouabain on the L-Glu-induced response (Fig. 4*b*). Perfusion of L-Glu immediately after addition of ouabain showed no immediate change in the L-Glu induced depolarization and repolarization (Fig. 4*b*). With continued exposure to ouabain, however, there was a progressive decrease in the size of the initial depolarization due to L-Glu and the subsequent repolarization. This is likely to be a result of the gradual dissipation of the Na$^+$ gradient that occurs in these cells in response to ouabain[15]. Thus, the repolarization is not directly involved with activation of an electrogenic Na$^+$/K$^+$ pump, which should have been immediately inhibited by ouabain. Possible alternative mechanism for the repolarization could include receptor desensitization or an increased K$^+$ conductance. However, the Na$^+$/K$^+$ pump in these cells clearly has an electrogenic component as shown by the small initial, ouabain induced depolarization (4 mV) and by the large (30 mV) transient hyperpolarization seen when ouabain was removed (Fig. 4*b*). This large transient hyperpolarization is presumably caused by Na$^+$ loading of the cells in the presence of ouabain, causing increased activation of the electrogenic component of the Na$^+$/K$^+$ pump after removing the ouabain[16].

The L-Glu-induced depolarization of cells shown to contain GFAP, the block of this response by Na$^+$ removal, and the depolarization caused by L- or D-Asp and KA all show that astrocytes in primary culture are directly depolarized by excitatory amino acids via a Na$^+$-dependent mechanism. This conclusion differs from that inferred from previous studies both *in vivo* and *in vitro*, where depolarization of glial cells was either not seen after L-Glu application[3,4], or, when it was observed, was ascribed to increased external K$^+$ released from stimulated neurones[5,6]. However, the depolarization caused by L-Glu of non-excitable cells in guinea pig cortical slices, also attributed to increased external concentration of K$^+$, was followed by a distinct hyperpolarization[17]. This is similar to the response we have invariably observed in cultured astrocytes, suggesting that this effect may indeed occur in the mammalian CNS *in situ.* Also, L-glutamate-induced depolarization of non-mammalian glial cells from axon-free *Necturus* optic nerve[18] and Schwann cells of axon-free squid giant nerve fibre sheaths[19] has also been observed suggesting that this response is a highly conserved glial property. The present findings of amino acid-induced depolarization of astrocytes in culture can now be added to a growing list of neurotransmitter induced effects in glial cultures of which the majority have been identified by changes in cellular cyclic AMP content or by ligand binding studies[20-24]. However, α-adrenergic receptor induced depolarization of glia in explant cultures[25] or of astroctyes in primary cultures[26] has also been observed, as well as a tetrodotoxin-sensitive, veratridine-induced Na$^+$ channel in primary astrocyte cultures[11]. It thus appears that the membrane potential of astrocytes, and other glial cells[18,19], can no longer be thought of as being responsive only to changes in external K^+ concentrations[27].

This work was supported by grants NS19492 from NINCDS and BNS 821873 from NSF to H.K.K. We thank Dr J. Huston for bovine GFAP, Dr G. Banker for neuronal hippocampal cultures and Dr P. Del Vecchio for use of his Nikon Labophot microscope and goat anti-mouse IgG. We thank Drs C. J. Frangakis (Sterling-Winthrop Research Institute, Rensselaer, New York), D. O. Carpenter, J. ffrench-Mullen, D. Martin, N. T. Slater, J. Swann and R. Waniewski (New York State Division of Research Laboratories, Albany, New York) for helpful comments. We also thank Mrs M. V. Frangakis for growing the cell cultures and Mrs E. P. Graham for typing the manuscript.

Cyclic GMP has been implicated as a messenger molecule involved in visual transduction[1]. Photoexcited rhodopsin (R*) binds to a multisubunit membrane protein called transducin (T) and stimulates the exchange of a bound GDP molecule for GTP. This leads to the release of the α-subunit of T with bound GTP (T_α–GTP), which activates a cyclic GMP phosphodiesterase[2–6]. The question arises as to whether the hydrolysis of cyclic GMP that results from activation of the phosphodiesterase is sufficiently rapid to be involved in visual excitation, which occurs on a time scale of ~2 s in the single-photon limit[7]. Previous studies have suggested that the cyclic GMP phosphodiesterase is activated in less than 100 ms at moderate light levels[3,8,9]. We report here light scattering studies of magnetically orientated frog rod outer segments which show that a molecule of R* catalyses the activation of a molecule of T in about 1 ms. Thus, hundreds of molecules can be activated within the response time of vision in the single-photon limit, and the formation of T_α–GTP is fast enough for it to be a key step in visual transduction.

The near-infrared turbidity of rod outer segment (ROS) suspensions changes following excitation with a visible light pulse[10–16]. Kühn and co-workers[8] delineated three types of scattering changes by using reconstituted disk membranes containing different amounts of transducin: (1) an R* signal due to the bleaching of rhodopsin, (2) a binding signal due to the association of R* with T-GDP and (3) a dissociation signal due to the release of T-GTP from R* following GTP-GDP exchange. We have further analysed the physical basis and kinetics of the dissociation signal which is of interest because it arises from an amplified event in the cyclic nucleotide cascade. We magnetically oriented frog ROS fragments in a 6-kG field at 45° to an infrared beam (Fig. 1). We achieved a high degree of orientation because of the large diamagnetic anisotropy of the multiple transmembrane α-helices of rhodopsin[17–18]. The lattice spacing (29.5 nm) and intensities of the first four meridional orders of diffraction of these fragments are virtually the same as those of intact ROSs[19–20]. The lamellar organization of disks and the orientation of these ROS fragments (Fig. 1) allowed us to obtain new information concerning the activation of transducin. The amplitude dA of the light scattered at right angles on the left and right sides by a volume element dV located at P is given by the product of the scattering power $f(\mathbf{x})\,dV$ and a phase factor:

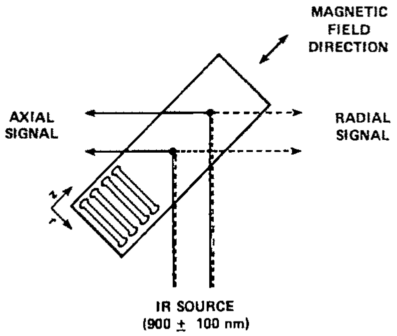

Fig. 1 Scattering geometry. ROS fragments in a 1-cm path length quartz cuvette were magnetically oriented at 45° to the incident 900±100 nm IR beam (900±100 nm). The intensity of light scattered at right angles to the incident beam was monitored by photodiodes located on the left and right sides by photovoltaic positive-intrinsic-negative diodes whose output was amplified, digitized and stored in 512 channels. The instrument response time was 0.1 ms. A photographic flash unit fitted with a 500-nm interference filter and a series of neutral density filters provided 0.5-ms light pulses to excite the sample via a light guide from below the curvette. ROSs obtained from the retinas of freshly dissected dark-adapted frogs (*Rana pipiens* and *Rana catesbieana*) were fragmented by being injected three times through a constricted 22-gauge hypodermic needle. This treatment made the plasma membrane sufficiently leaky to enable GTP to gain entry. These ROS fragments retained the native stacking of disks as judged by neutron scattering (measurement performed at ILL, Grenoble). A photodiode in the forward direction monitored the transmitted light intensity. The 500-nm excitation flash came from below via a light guide. Only axial changes (along the z direction) are seen by the detector on the left, whereas only radial changes (along the r direction) are seen by the detector on the right. The paths of the incident and scattered beams from scattering centres x and x' are shown

$$dA(\text{left}) = f(\mathbf{x}) \exp\left[-4\pi i z \sin(\pi/4)/\lambda\right] dV \quad (1)$$

$$dA(\text{right}) = f(\mathbf{x}) \exp\left[-4\pi i r \sin(\pi/4)/\lambda\right] dV \quad (2)$$

where z and r are the axial and radial coordinates, respectively, and λ is the wavelength of incident light. Now let dV move in the axial (z) direction from position $\mathbf{x}$ to $\mathbf{x}'$. It is evident from equations (1) and (2) that dA(left) will change because of the z-dependence of the exponential phase factor term, whereas

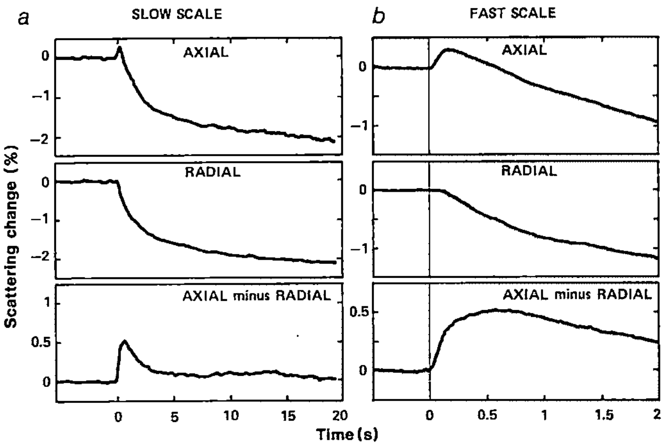

Fig. 2 Kinetics of the axial and radial light scattering changes and of their difference. A light pulse at $t=0$ produced $R^*=3.4\times10^{-4}$ (mol fraction). The sample contained about 10^6 ROS fragments (obtained from one retina) in 2 ml Ringer's solution (102 mM NaCl, 2.7 mM KCl, 1.9 mM $CaCl_2$, 2.1 mM $MgSO_4$, 2 mM $NaHCO_3$, 0.36 mM NaH_2PO_4, *p*H 7.4), 0.5 mM GTP, 23 °C. *a*, Slow time scale; *b*, fast time scale. The axial signal has a fast and a slow component whereas the radial signal has only the slow component. The slow scattering decrease has the same magnitude (2%) and decay time (4 s) in both axial and radial signals. *a*, *b* Bottom panels, axial signal minus the radial signal showing the rapid axial component alone. This signal has a rise time (initial time constant of the rising phase) of 100 ms and a decay time (initial time constant of the falling phase) of 4 s.

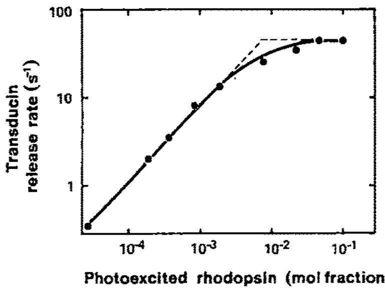

Fig. 3 Dependence of the transducin release rate on the mol fraction of photoexcited rhodopsin. GTP concentration, 0.5 mM. The release rates were determined from the slopes of the rise of the axial minus radial signals (for example, the bottom panel of Fig. 2*b*).

d*A*(right) will stay the same. Conversely, if d*V* is moved along the radial direction, d*A*(right) will change, whereas d*A*(left) will stay the same because the optical path length is unaltered. Thus, the detector on the left side monitors displacements in the axial direction only, whereas the one on the right side monitors displacements in the radial direction only. A displacement of molecules within the ROS fragment can be distinguished from a loss of molecules into the large aqueous space surrounding the fragments. In that event, $f(x)$ will be less and so d*A*(left) and d*A*(right) will decrease equally. A loss of scattering material from ROS fragments also leads to an increase in the intensity of transmitted light as monitored by a detector in the forward direction. A more detailed discussion of the characteristics of this θ-2θ scattering experiment is given elsewhere[24].

The light scattering changes produced by a light pulse forming 3.4×10^{-4} R* in the presence of 0.5 mM GTP are shown in Fig. 2. The axial signal is a combination of two components: a fast, transient scattering increase and a slow scattering decrease. The radial signal, in contrast, shows only a slow scattering decrease (Fig. 2). This slow decrease exhibits a lag of the same duration as the rise of the rapid axial signal.

The rapid axial increase in scattering probably arises from the release of transducin from the disk membrane surface into the inter-disk space following its activation to the GTP form. The decrease in scattering seen in both the radial and axial signals is probably due to the loss of soluble transducin from the ROS fragments. This loss of scattering material reduces the contrast between the ROS fragment and the surrounding medium by decreasing the refractive index of the fragment and slightly increasing that of the medium. Hence, a general decrease in scattering is observed in all directions. We will refer to the rapid axial increase as the release signal and to the slow decrease as the loss signal. The loss signal is 20-30 times larger than the release signal because the 900-nm incident beam is more effective in probing changes occurring on the scale of hundreds of nanometres than of a few nanometres. Several lines of evidence support this interpretation. (1) The release signal and loss signal show the same dependence on nucleotide and R* as does the activation of transducin. GTP or a hydrolysis-resistant analogue such as GTPγS or GppNHp is required for the appearance of both signals. ATP, GDP and GMP are ineffective. The amount of R* needed to elicit these signals is much less than the amount of transducin, indicating that R* has a catalytic role in the generation of these signals. (2) A release of transducin into the inter-disk space would give the observed exclusively axial signal because such a movement changes the *z* but not the *r* coordinate of the scattering units. (3) A loss of transducin from the ROS fragments would decrease the axial and radial scattering equally, as observed, because such a movement removes scattering material and thereby lowers the scattering density. (4) Complementary information was obtained by monitoring the intensity of transmitted light with a detector in the forward direction. An increase in the relative intensity of transmitted light having the same time course and amplitude as the loss signal was observed. This increase is the complement of the decrease observed by the left and right detectors, confirming that this signal is due to the loss of scattering material (T-GTP) from the ROS fragments. (5) Supernatants of ROS fragment suspensions illuminated in the presence of GTPγS contained all three subunits of transducin, as shown by SDS-polyacrylamide gel electrophoresis. In the absence of GTPγS or illumination, transducin remained bound to the ROS fragments, as expected from previous studies[21]. (6) Small ROS fragments (<10 μm in length) separated from large ones by centrifugation display a more rapid loss signal, as would be expected if their plasma membranes were rendered more leaky by extensive shearing. The kinetics of the release signal, in contrast, are independent of fragment size. (7) The loss signal exhibits a lag that matches the rise of the release signal. These signals are coupled because transducin must be released into the inter-disk space before it can leak out of the ROS fragment.

The loss signal corresponds to the dissociation signal observed by Kühn *et al.*[8] in their light scattering study of isotropic suspensions of homogenized bovine ROSs. The kinetics of their dissociation signal (~100 ms) was more rapid than the kinetics of our loss signal because of the small size and absence of a barrier to diffusion in their photoreceptor fragments.

The rise time of the release signal depends on the concentration of photoexcited rhodopsin. The rate of release *k*, expressed in units of mol fraction transducin released per s, is given by $k=\beta/\alpha$, where β is the maximal slope of the rise of the release signal (measured from the axial minus radial signal and expressed in units of % scattering change per s), and α is its maximal amplitude (% scattering change) in saturating conditions (1% bleach and 0.5 mM GTP). The dependence of the transducin release rate on the concentration of R* is shown in Fig. 3. The release rate is linearly proportional to R* at low light levels, ranging from $0.35\ s^{-1}$ at $R^*=3.6\times10^{-5}$ to $13\ s^{-1}$ at $R^*=1.8\times10^{-3}$. The number of molecules of transducin activated by a molecule of R* can be calculated from the slope of the linear region of the release rate versus R* plot. A release rate of $1\ s^{-1}$ at $R^*=10^{-4}$ corresponds to 1,000 molecules of transducin activated per s per molecule of R*, because the molar ratio of rhodopsin to transducin is 10. Thus, a molecule of transducin is activated to the GTP form by a molecule of R* in ~1 ms. At high light levels, the release rate becomes independent of R*, reaching a maximal value of $45\ s^{-1}$, which corresponds to a rise time of 22 ms. This limit is imposed by a step after the formation of metarhodopsin II, the photolytic intermediate that serves as R* (refs 22, 23), which occurs in 2 ms in our experimental conditions (23 °C).

It is of interest to compare the rate of activation of transducin with the kinetics of visual excitation. In the single-photon limit, the closure of sodium channels and consequent hyperpolarization of the plasma membrane are relatively slow, occurring in times of 1-2 s[7]. Extrapolation of our measurements to the single-photon limit shows that a single molecule of R* can activate 500 molecules of transducin in 0.5 s. Hence, the activation of transducin to the GTP form and its release into the inter-disk space occur sufficiently rapidly to enable T-GTP to serve as an amplified intermediate in visual excitation.

This work was supported by research grants from the National Eye Institute and the National Institute of General Medical Sciences (to L.S.) and the Comité des Membranes Biologiques, DGRST (to M.C.). T.M.V. was the recipient of an NIH training grant award (GM-07276).

Electrogenic Na–Ca exchange in retinal rod outer segment

King-Wai Yau & Kei Nakatani

Department of Physiology and Biophysics, University of Texas Medical Branch, Galveston, Texas 77550, USA

Previous work has suggested that a Na–Ca exchanger may have a key role in visual transduction in retinal rods[1–10]. This exchanger is thought to maintain a low internal free Ca^{2+} concentration in darkness[4–10] and to contribute to the rod's recovery after light by removing any internally released Ca^{2+} (refs 1, 2, 6–8). Little else is known about this transport mechanism in rods. We describe here an inward membrane current recorded from single isolated rods which appears to be associated with such external Na^+-dependent Ca^{2+} efflux activity. External Na^+, but not Li^+, could generate this current; high external K^+ inhibited it while small amounts of La^{3+} (10 μM) completely abolished it. The exchanger can also transport Sr^{2+}, but not Ba^{2+} or other divalent cations. The exchange ratio was estimated to be $3Na^+ : 1Ca^{2+}$. As well as demonstrating clearly the Na–Ca exchanger in the rod outer segment, our experiments also cast serious doubt on the commonly held view that light simply releases internal Ca^{2+} to bind to and block the light-sensitive conductance.

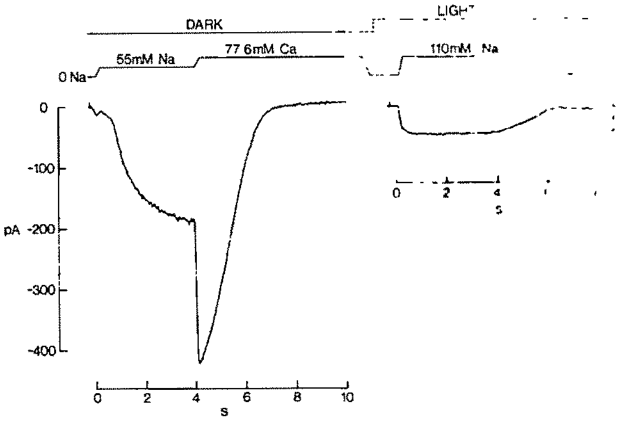

Fig. 1 Electrogenic Na^+-dependent Ca^{2+} efflux, or Na-Ca exchange, recorded from a toad rod after Ca^{2+} loading. Under infrared light a piece of retina from a dark-adapted toad (*Bufo marinus*) was finely chopped in Ringer's solution, yielding some isolated rods with intact outer and inner segments[7]. Membrane current from one of these rods was recorded by sucking its inner segment into a close-fitting glass pipette containing Ringer's solution while its outer segment was rapidly perfused[6,8,9]. Recordings were made with a current-to-voltage converter connected to the suction pipette. Time courses of solution changes, as indicated by junction currents[7], were ~200 ms and are shown above the sweeps. The valve controlling solution changes was operated pneumatically and with electronic timing so that the solution changes could be exactly reproduced many times. The exchange current was measured as the difference in recorded current on restoring Na^+ to a Na^+-free solution, done in light before and after the Ca^{2+} load. The light-sensitive current in darkness was obtained as the difference between total current recorded in darkness (light-sensitive current plus junction current) and junction current recorded in a repeated run in light. Outward membrane current across the outer segment is plotted upwards on the ordinate scale. All solutions except the isotonic (77.6 mM) Ca^{2+} solution contained ~1 μM buffered Ca^{2+}, with the following composition (in mM): 110 Na^+ or choline in partial or full substitution, 2.5 K^+, 1.5 Mg^{2+}, 0.093 Ca^{2+}, 119.7 Cl^-, 2 Mg-EDTA, 5 TMA (tetramethylammonium)–HEPES, 5 dextrose, *p*H 7.6. The isotonic Ca^{2+} solution contained (in mM): 77.6 $CaCl_2$, 5 TMA–HEPES, 5 dextrose, *p*H 7.6. The time lapse between Ca^{2+} loading and subsequent extrusion was ~26 s. Recordings were low pass-filtered at 100 Hz, 8-pole; room temperature. Steady light for junction current and exchange current measurements delivered about 800 photons (500 nm) $\mu m^{-2}\ s^{-1}$, unpolarized. Dark Ca^{2+} loading was 588 pC, or $\sim 1.8 \times 10^9$ Ca^{2+} ions.

We recorded the Na–Ca exchange current from an isolated, dark-adapted rod after its outer segment was loaded with Ca^{2+} (Fig. 1). Ca^{2+} loading was readily achieved as the light-sensitive conductance was highly permeable to divalent cations, especially after initial exposure to a Na solution containing low Ca^{2+} (refs 7, 9, 10). In order to isolate the exchange current, the recording was made normally in the presence of light which completely shut off the light-sensitive conductance; this conductance is thought to be the only ionic conductance in the plasma membrane of the outer segment[11,12]. The current, which was inward and transient, was seen only after the outer segment was loaded with Ca^{2+}, and not with monovalent cations such as Na^+, K^+ or Li^+. However, loading with Sr^{2+} (but not Ba^{2+} or other divalent cations such as Mg^{2+} or Mn^{2+}) also induced a similar current. We observed detectable but substantially smaller inward currents when much smaller Ca^{2+} or Sr^{2+} loads were effected by omitting the initial exposure to low external Ca^{2+} before introducing isotonic Ca^{2+} or Sr^{2+}.

The size of the current depends on the transmembrane electrochemical gradients for both Na^+ and Ca^{2+}, and the total charge transfer due to the current appears to depend only on the Ca^{2+} load (Fig. 2). These observations suggest that the current is associated with electrogenic Na^+-dependent Ca^{2+} efflux rather than ion movement through a novel membrane conductance being turned on by a rise in internal Ca^{2+} (ref. 13). The inward direction of the current suggests that more than two Na^+ ions enter the outer segment in exchange for each Ca^{2+} ion extruded. Assuming that the Ca^{2+} load is entirely removed

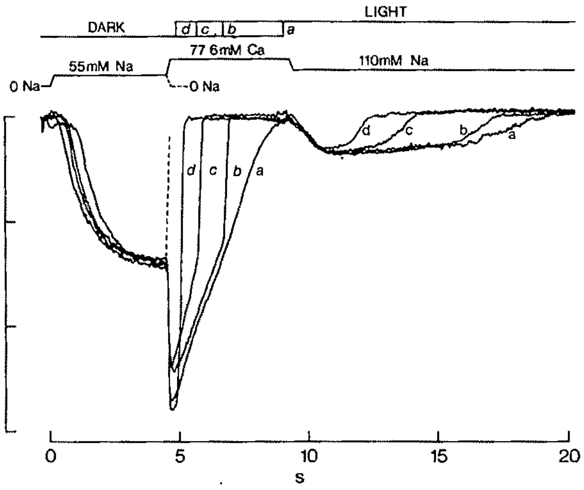

Fig. 2 Dependence of Na-Ca exchange current on size of Ca^{2+} load. The Ca^{2+} load was controlled by light which completely shut off the dark Ca^{2+} influx at various times, as shown by traces *a*–*d*. All records are from the same cell. All solutions and experimental conditions were the same as in Fig. 1, the only other difference being that the Na^+-free solution was not interposed between the 77.6 mM Ca^{2+} and the 110 mM Na^+ solutions in order to minimize the time lapse between Ca^{2+} load and subsequent extrusion. The broken line indicates the time course of decline of the Na^+ current if 0 Na^+ 110 mM Choline is introduced instead of 77.6 mM Ca^{2+}. The Ca^{2+} loads (Q_{load}) were *a*, 562; *b*, 404; *c*, 230; and *d*, 139 pC, equivalent to $\sim 1.7 \times 10^9$, 1.2×10^9, 6.9×10^8 and 4.2×10^8 Ca^{2+} ions respectively. The charge ratios $Q_{load}/Q_{exchange}$ were *a*, 2.38; *b*, 2.02; *c*, 1.87; and *d*, 2.43 (mean 2.18). This ratio is related to the stoichiometry (n) of the exchange (that is, n Na^+ : 1 Ca^{2+}) by $Q_{load}/Q_{exchange} = 2/(n-2)$. Hence n was 2.92. From 18 experiments the average value of n was 2.94 ± 0.10 (±s.d.). (In Figs 1 and 3, n was not computed because of the relatively long time between Ca^{2+} loading and readmission of external Na^+ (26–111 s). Other experiments have indicated that a long time lapse tends to allow some of the Ca^{2+} influx to slowly leave the outer segment via an alternative route, most probably by diffusion into the inner segment (see also ref. 8).) Steady light delivered 300 photons (500 nm) μm^{-2} s^{-1}, unpolarized; this produced $\sim 4.5 \times 10^3$ photoisomerizations s^{-1}, assuming an effective collecting area of 15 μm^2 (see ref. 22). Light itself should also trigger some Ca^{2+} efflux even in the absence of Ca^{2+} loading[1,2,8]. From estimates obtained by others[1,2,8], this additional efflux even at high light intensities is unlikely to be over 10^7 Ca^{2+} ions s^{-1}, corresponding to an inward exchange current of ~1.6 pA. However, most of this current should already have been subtracted from the records because each record was obtained as the difference between two runs in the same light conditions (Fig. 1 legend). As the exchange current induced by a Ca^{2+} load as reported here is typically 30–40 pA, the error introduced to the above analysis by the light-triggered Ca^{2+} efflux should be less than a few per cent.

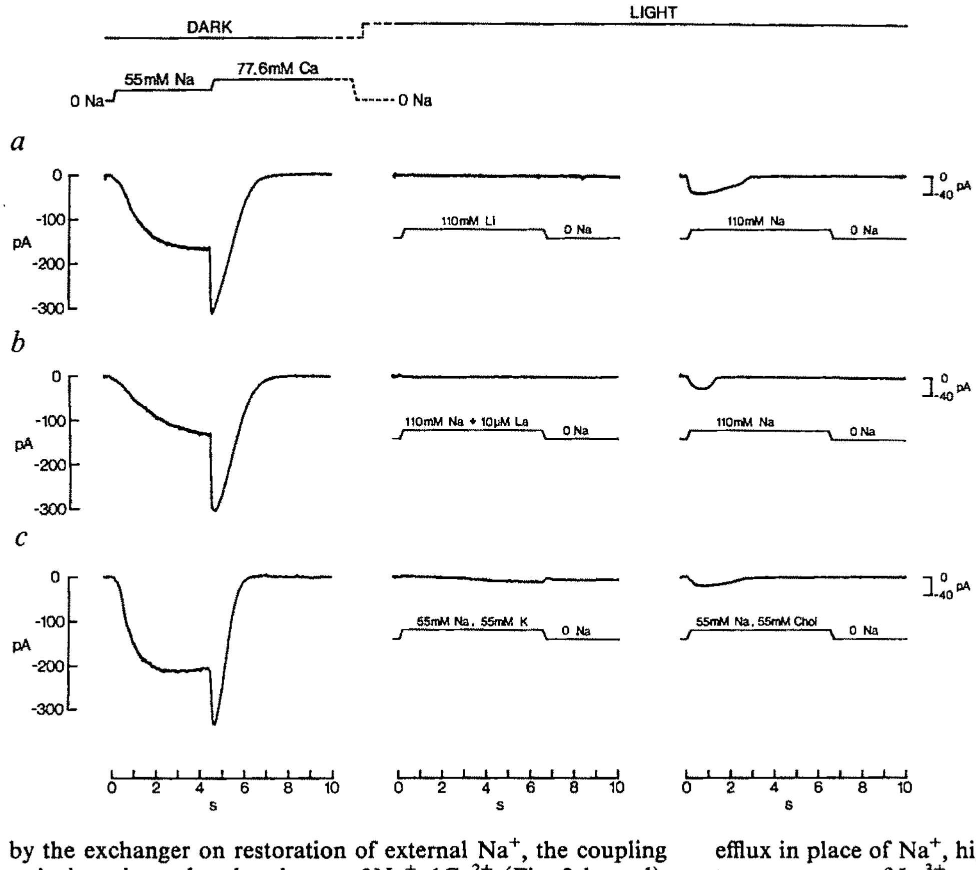

Fig. 3 Effects of external Li^+, La^{3+} and K^+ on the Na-dependent Ca^{2+} extrusion. Three different cells in *a*, *b* and *c*. In each experiment, the test solution containing Li^+, La^{3+} or high K^+ was followed by a control Na^+ solution. *a*, *c*, Na^+ (including 0 Na^+) and Li^+ solutions identical in composition to those in Fig. 1 with a buffered Ca^{2+} concentration of ~1 μM. *b*, Na^+ solutions contained nominally (that is, unbuffered) zero Ca^{2+} as follows (in mM): 110 Na^+, 2.5 K^+, 1.6 Mg^{2+}, 0 Ca^{2+}, 115.7 Cl^-, 5 TMA-HEPES, 5 dextrose, pH 7.6. Time lapse between Ca^{2+} load and admission of test solution: *a*, 37 s; *b*, 57 s; *c*, 33 s. Time lapse between Ca^{2+} load and admission of control Na^+ solution: *a*, 73 s; *b*, 111 s; *c*, 51 s. Steady light delivered 800 Photons (500 nm) μm^{-2} sec^{-1}, unpolarized.

by the exchanger on restoration of external Na^+, the coupling ratio is estimated to be close to 3Na^+ : 1Ca^{2+} (Fig. 2 legend). Since the Ca^{2+} loading and the subsequent extrusion by the exchanger could be repeated reversibly many times on the same cell, the above assumption seems reasonable. It has previously been suggested[2] that an uncoupled Ca^{2+} efflux might also exist at the outer segment; such a mechanism should generate an outward membrane current, however, which we have not detected. If present, this uncoupled Ca^{2+} efflux probably saturates at very low capacity and produces an outward current too small to be detected in our experimental conditions. The exchange ratio of 3 Na^+ : 1 Ca^{2+} is similar to some estimates obtained from other types of cells[14,15].

We have examined several properties of this exchange current (Fig. 3) and found that external Li^+ cannot support the Ca^{2+} efflux in place of Na^+, high external K^+ inhibits the efflux, and trace amounts of La^{3+} completely abolish it. These results confirm indirect evidence from earlier experiments about the actions of these ions on rods[4–7,9,10,16] and they suggest also that this exchanger in rods may share some similar properties with that found elsewhere, for example squid axon[17,18].

One striking feature of the Na-Ca exchanger in rods is its large Ca^{2+} pumping capacity. In the experiment of Fig. 1, for example, calculations show that the Ca^{2+} influx during exposure to isotonic Ca^{2+} should have increased the total Ca^{2+} concentration within the outer segment by ~2 mM; yet it took the exchanger only seconds to remove this excess Ca^{2+} and allow recovery of the cell. We observed rather similar effectiveness in pumping when a normal (1 mM) instead of low Ca^{2+} concentration was present externally during Ca^{2+} extrusion. In normal circumstances, when the steady Ca^{2+} influx through the light-sensitive conductance in darkness is likely to be relatively small[9,10], the exchanger should run well below its maximal capacity.

Collective evidence so far[4,5,7,9,10,19-21] has clearly indicated that a rise in internal Ca^{2+} somehow leads to the blockage of the light-sensitive conductance. In view of this, it is rather surprising that the large Ca^{2+} current in, for example, Fig. 1 switches off relatively slowly despite a peak influx of as many as 10^9 Ca^{2+} ions s^{-1}; thus, the current declines only by ~50 % after 1.4×10^9 Ca^{2+} ions have entered. It might be argued that Ca^{2+} buffering within the rod outer segment is so extremely rapid and powerful as to be able to maintain low internal free Ca^{2+} despite this very large influx. This, however, seems highly unlikely because we found that much smaller Ca^{2+} loads in the same conditions also led to a large increase in exchange current in darkness (data not shown), suggesting a rapid rise in free Ca^{2+} within the outer segment. Internal Ca^{2+} most probably does not act by binding directly to and blocking the conductance, or perhaps it requires additional cellular substrates to express fully its blocking action. In contrast, the large Ca^{2+} current could be completely shut off within ~300 ms by light at an intensity causing about 5×10^3 photoisomerizations s^{-1} in the rod outer segment (Fig. 2). From other estimates[1,2,8], any rise in internal free Ca^{2+} triggered by the light during this period is probably only ~10^7 ions, far less than that caused by the Ca^{2+} influx through the light-sensitive conductance. This suggests that the ability of light to block the conductance results from its modulation of other cellular substrates which act more directly or perhaps more effectively on the conductance.

Abrogation of resistance to bone marrow transplantation by induction of specific tolerance in natural killer cells?

Martin Waterfall, Lee S. Rayfield & Leslie Brent

Department of Immunology, St Mary's Hospital Medical School, Paddington, London W2 1PG, UK

Hybrid resistance describes the capacity of first generation (F_1) hybrids between certain mouse strains to inhibit the growth of tumour or haematopoietic cells of parental origin[1,2]. The cells that appear to mediate this phenomenon differ from classical T and B lymphocytes in several respects. For example, they are unusually radioresistant[3], show no immunological memory[4], are present in thymectomized[5] or congenitally athymic[6] mice, and are not functional until about 3 weeks after birth[3,4]. These characteristics suggest that the effectors are natural killer (NK) cells[7]. Although most of the evidence implicating NK cells in hybrid resistance is circumstantial, the experiments of Warner and Dennert[8] are more direct in that they show that resistance can be restored to mice with a congenital or induced defect in NK activity by the infusion of cells belonging to an NK clone. Conversely, treatment of mice with an antibody to NK cells abrogated hybrid resistance to parental bone marrow grafts[9]. Both NK cells and the effectors of hybrid resistance are generally considered to be nonspecific. We have now investigated this assumption by attempting to prevent hybrid resistance by neonatal tolerance induction with parental strain antigens. Our data indicate that hybrid resistance can be abrogated by this means and that the tolerance is specific and transferable with Thy-1⁺ spleen cells.

Groups of (CBA/Ca × C57BL/Gr)F_1 hybrid mice ($H\text{-}2^{k/b}$) received varying doses of adult C57BL/Gr bone marrow cells intraperitoneally within 24 h of birth and were tested 2–3 months later for their capacity to resist the engraftment of parental or F_1 hybrid bone marrow cells following lethal whole body irradiation (8.0 Gy). The 'take' of the grafts was assessed by the incorporation of ^{125}I-labelled 5-iodo-2′-deoxyuridine in the recipient spleens (see Fig. 1 legend for experimental details).

Hybrid resistance is clearly demonstrated in Fig. 1. Normal F_1 recipients of C57BL bone marrow failed to incorporate significant levels of the label (Fig. 1*c*) compared with mice that had received syngeneic F_1 cells (Fig. 1*a*). The neonatal inoculation of C57BL cells had no effect on the engraftment of F_1 cells (Fig. 1*b*) but prevented rejection of C57BL cells (Fig. 1*d*). Although in this experiment the take of C57BL bone marrow cells was virtually the same as that of F_1 cells, it tended to be lower in most other experiments (see Fig. 2). Neonatal exposure to parental strain bone marrow antigens thus had a profound effect on the development of hybrid resistance. Unexpectedly, cells from the SJL/J strain ($H\text{-}2^s$), which are likewise rejected by (CBA × C57BL)F_1 mice (Fig. 1*e*), were unaffected by the tolerance (Fig. 1*f*). This result, which has been obtained consistently in eight separate experiments, shows conclusively that the tolerance mechanism operative in this system is strain specific and suggests that haematopoietic resistance is mediated by more than one population of effector cells.

The dose of cells inoculated neonatally varied between 1.0 and 4.0×10^7. The data in Fig. 1 were based on 1.5×10^7 cells, but in the other seven experiments 4.0×10^7 cells were used; we have found that 1×10^7 cells are inadequate (data not shown). Female recipients were generally more resistant to tolerance induction: 1.5×10^7 induced tolerance in only some females but 4×10^7 secured tolerance in all.

Three attempts to break tolerance by the adoptive transfer of 10^8 normal syngeneic F_1 hybrid spleen cells were unsuccessful, suggesting that tolerance is maintained by active suppression. We therefore injected 10^8 spleen cells from tolerized mice into normal syngeneic F_1 animals to ascertain whether tolerance in hybrid resistance is transferable. The cell recipients were irradiated 6 days after cell transfer and received the indicator bone marrow grafts on the following day (see Fig. 2 legend). As found in previous experiments, hybrid resistance to C57BL grafts was abrogated by neonatal tolerance induction (Fig. 2, compare *a*, *b* and *c*). The adoptive transfer of cells from tolerant donors conferred unresponsiveness to C57BL (Fig. 2*d*) but not to SJL (Fig. 2*e*) cells. Pretreatment of the cells with a monoclonal anti-Thy-1.2 antibody and complement completely prevented the transfer of tolerance (Fig. 2*f*), showing that Thy-1⁺ cells, presumably T lymphocytes, are required. Similar results have been obtained in three other experiments.

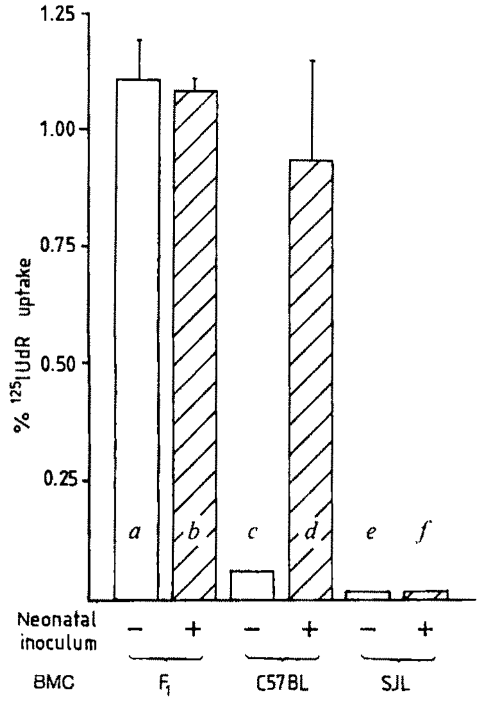

Fig. 1 Abrogation of hybrid resistance in (CBA×C57BL)F_1 hybrid mice by the neonatal inoculation of C57BL bone marrow cells (BMC). 8-12-week old hybrid mice that had received 1.5×10^7 C57BL bone marrow cells intraperitoneally (i.p.) within 24 h of birth (groups *b, d, f*) were used to measure hybrid resistance. Groups of four male mice were exposed to 8.0 Gy whole body X-irradiation and given intravenously (i.v.) 5×10^5 bone marrow cells from F_1 hybrid (*b*), C57BL (*d*) or SJL (*f*) donors (tolerized animals shown as hatched bars in this and other figures). Controls were provided by non-tolerized and sex and age-matched F_1 hybrids (*a, c, e*) given the same types of cells, respectively. Engraftment of donor cells was assessed by measuring the incorporation of ^{125}I-labelled 5-iodo-2′-deoxyuridine (^{125}IUdR) in the recipient spleens[17] as follows. Five days after bone marrow cell transplantation, the mice were given a single i.p. dose of 25 μg 5-fluorodeoxyuridine to decrease the availability of endogenous thymidine. This was followed 1 h later by 0.5 μCi ^{125}IUdR i.p. Spleens were removed 18-24 h later and counted in a Packard γ spectrometer. ^{125}IUdR uptake was calculated as the % of total radioisotope injected. Geometric means and standard deviations of the arithmetic means are shown for each group. In some experiments (though not in the experiment shown here), engraftment of parental CBA cells was also evaluated: such data were always comparable to the syngeneic controls.

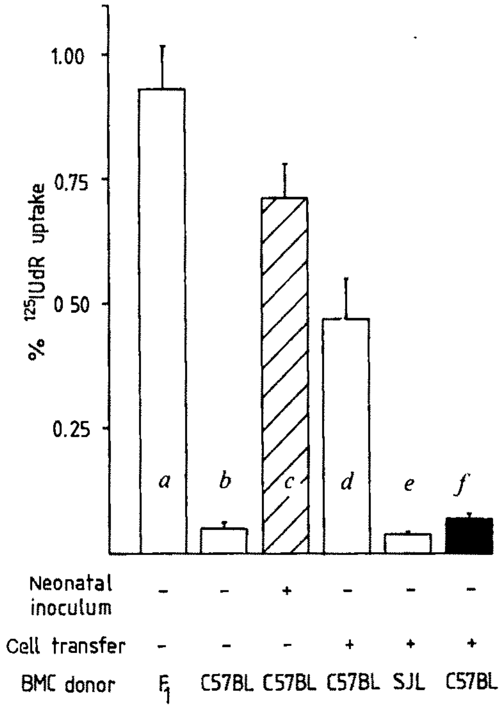

Fig. 2 Suppression of hybrid resistance by the adoptive transfer of spleen cells from tolerant mice. Tolerant F_1 hybrid donors were prepared as described in Fig. 1 legend except that the tolerizing inoculum consisted of 4×10^7 C57BL bone marrow cells. 10^8 spleen cells from tolerized donors were injected i.v. into normal adult (CBA×C57BL)F_1 mice 6 days before lethal whole body irradiation (groups *d-f*), followed 1 day later by 5×10^5 C57BL bone marrow cells given i.v. Group *f* received spleen cells that had been pretreated by two exposures to a monoclonal IgM anti-Thy-1 antibody and guinea pig complement[16]. Control mice were either normal (*a, b*) or neonatally tolerized (*c*) F_1 hybrids. Resistance to engraftment by C57BL (*b-d, f*) or SJL (*e*) cells was assessed by ^{125}IUdR uptake (see Fig. 1 legend) and compared with controls given syngeneic bone marrow cells (*a*). All groups comprised four mice.

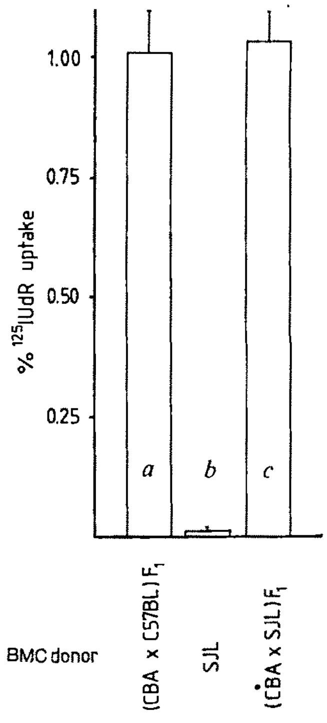
Our study raises the question of the antigens involved in hybrid resistance. Genetic analysis by Cudkowicz and Nakamura[10] has shown that in certain mouse strains the expression of hybrid resistance is controlled by a number of *Hh* (haematopoietic histocompatibility) loci, some of which are linked to *H-2*, the major histocompatibility complex (MHC) of the mouse. *Hh* products seem to be expressed only in homozygous inbred strains. Both C57BL and SJL strains express products of the *Hh-1* locus which are thought to be highly cross-reactive, if not identical[11]. The specificity we have encountered is therefore all the more intriguing. One important difference between the antigenic relationship of the two strains to their hybrid hosts is that SJL cells are completely histoincompatible, whereas C57BL cells are not. It could therefore be argued that mechanisms other than those mediating NK activity are involved in hybrid resistance to allogeneic haematopoietic grafts, although it is generally accepted that the effectors responsible for resistance to allogeneic haematopoietic grafts in lethally irradiated animals are similar, if not identical, to those causing the rejection of parental cells[7].

In this connection, we have shown in two experiments (Fig. 3) that (CBA×SJL)F_1 bone marrow cells are not rejected by normal (CBA×C57BL)F_1 mice, indicating that conventional

Fig. 3 Resistance of (CBA× C57BL)F_1 hybrid mice to haematopoietic grafts presenting SJL strain MHC antigens. Engraftment of bone marrow cells was determined in groups of four 8-12-week old (CBA× C57BL)F_1 hybrids following lethal irradiation and reconstitution with 5×10^5 bone marrow cells from syngeneic (group *a*), SJL (*b*) or (CBA×SJL)F_1 (*c*) mice as described in Fig. 1 legend.



SJL MHC antigens are unlikely to be the target of resistance. Another approach was to examine resistance to parental grafts in (C57BL×SJL)F_1 hybrids. In an early experiment we found that such hybrids accepted C57BL bone marrow cells following tolerance induction with C57BL cells but retained resistance to bone marrow from SJL mice (the other parental strain). However, other experiments on these lines showed such marked variability in the take of both parental and even of syngeneic F_1 hybrid cells that we cannot have confidence in this result.

Our experiments show that T lymphocytes can suppress hybrid resistance, but we have not excluded the possibility that resistance to parental and allogeneic bone marrow cells is mediated by the same nonspecific NK effector and that specificity is imparted by suppressor lymphocytes. Were this the case, it would be expected that SJL cells would take when transplanted in the same inoculum with C57BL cells, to (CBA×C57BL)F_1 hybrids that had been tolerized with C57BL antigens. Figure 4 illustrates that this is not the case. Here we have used two doses of bone marrow cells (2.5×10^5 and 2.5×10^6) to increase the sensitivity of the assay. SJL cells at the higher dose were mixed with C57BL cells at the lower dose and inoculated into tolerized (CBA×C57BL)F_1 recipients. The take of this mixture (Fig. 4*h*) was not significantly different from the take of 2.5×10^5 C57BL cells alone (Fig. 4*g*). If exposure to C57BL antigens had caused the activation of a suppressor cell specific for C57BL, which then acted on a nonspecific effector, the take of cells in group *h* should have been greater than that in group *d* (2.5×10^6 C57BL cells in normal recipients) and approaching the level of incorporation observed in group *b* (2.5×10^6 F_1 cells). These experiments therefore favour the notion that the effectors for SJL and C57BL are distinct in their specificity.

We believe this to be the first demonstration that hybrid resistance can be prevented by neonatal tolerance induction and that specific Thy-1^+ suppressor cells can apparently regulate the activity of NK cells *in vivo*. The specificity of the effector cells is compatible with the earlier report by Cudkowicz and Bennett[3] that adult (C3H×C57BL)F_1 hybrids (H-$2^{k/b}$) become specifically unresponsive to H-2^b bone marrow cells after multiple immunization with C57BL spleen cells. It is at variance with the recent observation (ref. 11 and I. Nakamura, personal communication) that homozygous H-2^s and H-2^b lymphoid cells were equally effective in abrogating resistance to C57BL bone marrow cells when given to (C57BL/6×DBA/2)F_1 adult mice shortly before irradiation and reconstitution. However, this apparent lack of specificity could be due to the use of a hybrid (H-$2^{b/d}$) different from that used by Cudkowicz and Bennett and by us (H-$2^{k/b}$): whereas the latter recognizes at least two epitopes of Hh antigens, one common to H-2^b and H-2^s strains and the other unique to H-2^s, the former may recognize only the common epitope. Unresponsiveness to the common determinant in (C57BL/6×DBA/2)F_1 mice could therefore be expected to allow the take of H-2^s as well as of parental grafts. Alternatively, the suppression rather than the effector mechanism might have been nonspecific in the system described by Nakamura.

It could be argued that the specificity of the NK cells is imparted by naturally occurring antibody, based on the model of Chow *et al.*[12] for NK surveillance against syngeneic tumours. Such an interpretation is virtually ruled out by the observation that hybrid resistance is intact in mice depleted of B lymphocytes by the neonatal administration of anti-μ antibody[13].

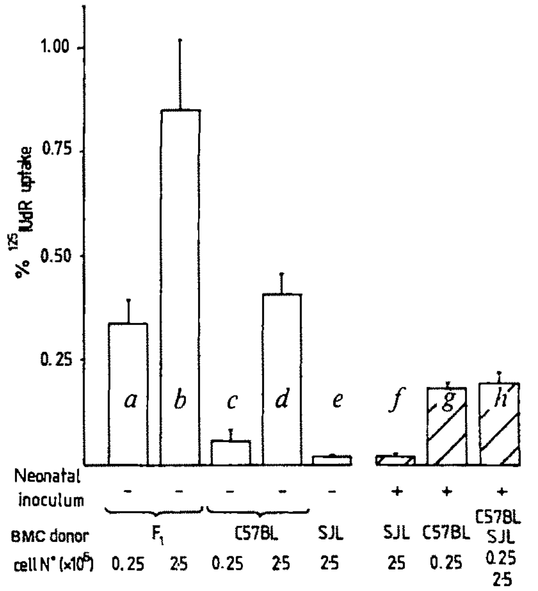


Fig. 4 Resistance of (CBA×C57BL)F_1 hybrid mice, tolerized neonatally to parental C57BL Hh antigens, to allogeneic SJL bone marrow cells injected as a mixture with C57BL bone marrow cells. (CBA×C57BL)F_1 mice tolerant to C57BL bone marrow cells were prepared as described in Fig. 2 legend (groups *f*–*h*). Groups of four 8–10-week old (CBA×C57BL)F_1 hybrids were lethally irradiated (8.0 Gy) and given i.v., 24 h later, bone marrow cells from F_1 (*a*, *b*), C57BL (*c*, *d*, *g*) or SJL (*e*, *f*) donors. Groups *a*, *c* and *g* were given 2.5×10^5 and groups *b*, *d* and *e* 2.5×10^6 cells. Group *h* received a mixture of 2.5×10^5 C57BL and 2.5×10^6 SJL cells. Engraftment was assessed 5 days after reconstitution as described in Fig. 1. Although we were unable to include SJL→SJL controls in this experiment to show that the SJL bone marrow cells take normally in susceptible hosts, we have found in five other experiments that this is indeed the case.

In conclusion, our evidence shows that resistance to parental and allogeneic haematopoietic grafts is mediated by different effector cell populations, presumed to be subpopulations of NK cells. Moreover, the effectors involved in hybrid resistance can be controlled by specific suppressor T cells. Our demonstration of specificity in hybrid resistance probably accounts for the unexplained finding by Warner and Dennert[8] that cloned NK cells from C57BL/6 mice did not establish resistance against C57BL/6 bone marrow grafts in NK-deficient (C57BL/6×C3H)F_1 hybrids (H-$2^{b/k}$), despite the fact that resistance to allogeneic BALB/c grafts (H-2^d) was restored.

Our model should enable us to examine the effect of tolerance induction on the activity of NK cells *in vitro*, as well as on the progression of syngeneic tumours, some of which seem to be subject to NK cell surveillance[8,14]. Finally our results make it highly probable that the transplantation of allogeneic bone marrow grafts *in utero*[15,16] should not be thwarted by fetal NK activity.

We thank the Wellcome Trust for their support of L.S.R. and the MRC for M.W.'s postgraduate studentship. We also thank Ms Beverley Whittle, Mrs Ellen Yanez and Mr M. Gevaux for their assistance and Professor W.L. Ford for helpful comments.

Characterization of cDNA for precursor of human luteinizing hormone releasing hormone

Peter H. Seeburg & John P. Adelman

Department of Molecular Biology, Genentech, Inc., 460 Point San Bruno Boulevard, South San Francisco, California 94080, USA

Human reproduction is controlled by the hypothalamic–pituitary–gonadal axis laid down early in fetal development. Luteinizing hormone releasing hormone (LHRH), also termed gonadotropin releasing hormone (GnRH), is a decapeptide[1,2] and is a key molecule in this control circuit. It is produced by hypothalamic neurones, secreted in a pulsatile manner into the capillary plexus of the median eminence and effects the release of luteinizing hormone and follicle stimulating hormone from gonadotropic cells in the anterior pituitary[3]. The peptide may have further functions, including behavioural ones[4], as LHRH or LHRH-like immunoreactivity has been found in gonadal tissue[5,6], placenta[7,8] and the central nervous system[9,10], and exogenously administered LHRH is shown to affect behaviour[11,12]. To investigate the biosynthesis of LHRH, we have now isolated cloned genomic and cDNA sequences encoding the precursor form of LHRH, the existence of which had been suggested from chromatographic studies of hypothalamic[8,13] and placental[8] extracts. These DNA sequences code for a protein of 92 amino acids in which the LHRH decapeptide is preceded by a signal peptide of 23 amino acids and followed by a Gly-Lys-Arg sequence, as expected for enzymatic cleavage of the decapeptide from its precursor[14–16] and amidation[17] of the carboxy-terminal of LHRH.

A genomic library was used in preference to cDNA libraries to initially screen for LHRH-encoding DNA sequences. The most important reasons for this choice were the anticipated low abundance of LHRH messenger RNA, the possibility of a very long 3′ untranslated region, and the unknown location of the decapeptide coding unit within the mRNA. Figure 1 shows the probe strategy used to screen the genomic library; it is described in the corresponding legend. Although a similar approach using a single long probe has led to the successful isolation of several genes[18–20], the available amino acid sequence in these cases had comprised more than 20 residues. The LHRH-coding sequences would only be isolated successfully if all members of the pool of long probes (Fig. 1 legend) were present, and if the correct nucleotide choices were incorporated into a sufficient number of the third-codon positions. To determine the pool composition and sequence, the oligonucleotide mixture was analysed by cloning in a phage M13 vector[21] (see Fig. 2 legend). Figure 2 shows the results of this analysis and demonstrates that, most importantly, all the nucleotide combinations of the long probes were represented. Thus, in spite of several deletions predominantly within the Tyr codon and a single nucleotide insertion in the same codon, the quality of the oligonucleotide mixture was considered satisfactory for screening a genomic library.

The probing of 10^6 λ phage containing human genomic DNA[22] produced ~300 positives with signal strengths ranging from barely visible to very strong. Only one of them hybridized to both the long and short probes. Figure 3 shows the analysis of this clone; the same single restriction fragments are seen to hybridize with both sets of oligomers (Fig. 3*a*). Figure 3*b* shows a sequencing gel indicating the hybridizing region. The amino acid sequence derived from the nucleotide sequence shows that this DNA indeed codes for the LHRH peptide. The DNA sequence also predicted the expected C-terminal Gly residue necessary for amidation[17] followed by a Lys-Arg processing site[14]. Although such a processing site had been expected to, but does not, precede LHRH (see Fig. 1), and although our long probes also differed in five nucleotides from the actual LHRH coding region (compare Figs 1 and 4), the sequence homology of these probes was sufficient to find the correct gene.

Fig. 1 Synthetic oligodeoxynucleotides for the isolation of LHRH coding sequences. The amino acid sequence of LHRH(1–10) (refs 1, 2) is shown with a conjectural sequence for part of the LHRH precursor (extended peptide). The three additional amino acid residues were incorporated on the assumption that LHRH is preceded in its precursor protein by a processing site in the form of a pair of basic amino acids[14] and that a Gly residue donates its amino group during C-terminal amidation[17]. The pyro-Glu is thought to be derived from Gln[44]. Based on this extended peptide sequence, a pool of eight oligonucleotides (long probes, 5′→3′) was synthesized[45] to be used as probes for the screening of a human genomic library. The degeneracy of these probes allowed for the two codon types for Arg (AGPu and CGX) and Ser (AGPy and TCX), but for only one of any two or four choices for all third-codon positions. The single choice of TTG for the Leu codon was based on evolutionary arguments[46]. The pool of 16 heptadecamers with a sequence complementary to that coding for amino acids 1–6 of LHRH (short probes, 3′→5′) was used to further select between the large number of genomic clones that hybridized with the long probes (J.P.A. *et al.*, in preparation). Filled circles represent one of two, and open circles one of four possible nucleotides in third-codon positions.

Fig. 2 Analysis of long probes. The double-stranded DNA shown is composed of the synthetic 38-mer pool (+) coding for the extended LHRH peptide (Fig. 1) and a complementary nonameric primer (both in bold print), together with the rest of the complementary strand (−) generated by enzymatic DNA synthesis (normal print). This DNA was molecularly cloned and 14 clones were sequenced. Only nucleotides in degenerate positions are shown above and below the double-stranded DNA. Hyphens denote missing nucleotides. The position of a GMP insertion found in the Tyr codon in one of the cloned DNAs is indicated.

Methods: 20 pmol of 5′-phosphorylated long probes were annealed with 40 pmol of 5′-phosphorylated nonameric primer in 40 µl of 20 mM Tris-HCl *p*H 7.5, 100 mM NaCl, 6 mM $MgCl_2$, 0.1 mM EDTA, 100 µM each of dATP, dGTP, dCTP, dTTP, at 14 °C for 15 min. DNA synthesis was initiated by the addition of 5 U *Escherichia coli* DNA polymerase I (large fragment, Boehringer Mannheim) and allowed to proceed for 30 min at 14 °C. Following phenol extraction and ethanol precipitation, the DNA was incubated for 2 h at room temperature with 10 ng *Sma*I-cleaved M13 mp10 RF-DNA[48] in 20 µl containing 50 mM Tris-HCl *p*H 8, 10 mM $MgCl_2$, 0.1 mM EDTA, 10 mM β-mercaptoethanol, 0.5 mM rATP and T4 DNA ligase (New England Biolabs). The ligation mixture was used to transform competent *E. coli* JM103 cells[21]. Recombinant phage was grown, single-stranded phage DNA prepared and sequenced using dideoxynucleoside triphosphates as described[21,47].

Because of the possible presence of introns in the gene, we isolated the corresponding cDNA to elucidate the complete structure of the LHRH precursor protein.

A 600-base pair (bp) DNA restriction fragment obtained from the genomic clone and containing the LHRH coding sequence (J.P.A. *et al.*, in preparation) was used as a probe to screen a large cDNA library constructed in λ phage[23]. As human hypothalami were not available to us, the cDNA was derived from human placental tissue where LHRH synthesis has been shown to occur[24]. Two hybridizing clones were isolated which contained cDNA inserts of ~1,500 and 800 bp in length. Figure 4 shows the complete nucleotide sequences of both cDNAs, together with the deduced amino acid sequence of the LHRH precursor protein.

The most prominent feature of the cDNA is a very long 5′ untranslated region of >1,000 nucleotides. A similarly sized 5′ region has been described for the human preproenkephalin B gene[25] but seems otherwise to be a rare phenomenon. As LHRH is expressed in various tissues, transcription of the precursor gene from different tissue-specific promoters[26] might be invoked to account for the presence of such an extended 5′ region in the placental cDNA[26,27]. The trivial explanation, that the clone is derived from an unspliced nuclear RNA, can be refuted because two introns present in the gene had been clearly removed (J.P.A. *et al.*, in preparation). The smaller of the two cloned cDNAs has ~400 nucleotides of 5′ untranslated sequence which also contain the best consensus splice acceptor site[28] (nucleotides 960-974), making the possibility of a partially spliced version unlikely. The very low abundance of the corresponding mRNA in placental tissue has so far precluded the use of Northern analysis[29] to establish the correct length of its 5′ region. Furthermore, complete co-linearity of this region with the established genomic sequence (J.P.A. *et al.*, in preparation) excludes artefacts which might have been introduced during reverse transcription and molecular cloning.

The largest open reading frame (nucleotides 1,063-1,350) specifies the coding sequence for LHRH and translates into a peptide of molecular weight ~10,000 with characteristics of a precursor for a polyfunctional protein (for review see ref. 30). This reading frame is terminated by an ochre stop codon and followed by 160 nucleotides of a 3′ untranslated region containing an AATAAA sequence for polyadenylation[27] shortly upstream of the poly(A) tail. The actual start of translation within the open reading frame is unclear. The first ATG initiation codon (position 1,063) is followed by an in-frame ATG four codons downstream. This second ATG, but not the first, is followed by a purine and preceded by an A at position −3, as is the case with most eukaryotic initiation codons[31]. We therefore consider this latter ATG at position 1,075 to be the most likely start codon for initiation of the synthesis of the LHRH precursor protein although it involves a violation of the rule which specifies that the first ATG should bear this function[32]. It is possible that both ATGs are involved in the initiation of protein synthesis, resulting in a low translational efficiency[31].

The first 23 amino acids form a typical signal sequence containing a hydrophobic middle section[33]. The putative signal sequence ends in two serine residues followed by the expected decapeptide sequence for LHRH[1,2]. Cleavage of the signal peptide results in an amino-terminal glutamic residue which spontaneously or enzymatically undergoes cyclization to pyro-Glu, the modified amino-terminus of LHRH[1,2]. The decapeptide sequence is followed by a glycine, the standard donor of the amino group for C-terminal amidation[17]. A Lys-Arg cleavage site is present for enzymatic processing, as is found in many precursors to neuroendocrine peptides[30]. Thus, the isolated cDNAs code for a true precursor protein to LHRH which features a direct linkage of signal sequence to biologically active peptide reminiscent of the situation in the precursor for vasopressin[34].

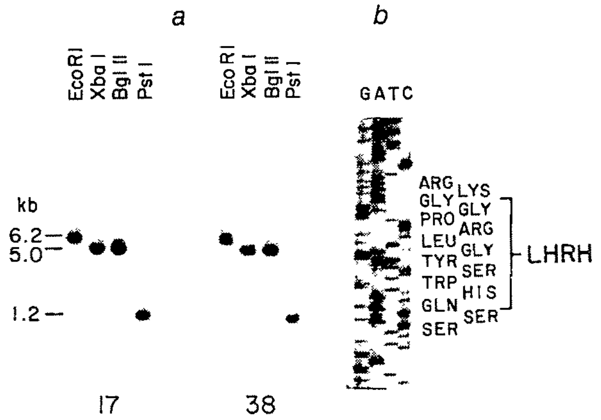

Fig. 3 Identification of a cloned human genomic DNA segment carrying LHRH coding sequences. Sequential screening of a human genomic library[22] with two pools of oligomers (long (38) and short (17) probes; see Fig. 1) yielded one isolate the DNA of which hybridized with both oligomeric probes. *a*, Southern analysis[40] of the DNA digested with four restriction endonucleases (*Eco*RI, *Xba*I, *Bgl*II, *Pst*I). DNA fragment sizes in kilobase pairs (kb) are indicated on the left and were assessed using *Hin*dIII-cleaved λ DNA (BRL). *b*, A sequencing gel (G, A, T, C) across the region of hybridization with both oligomer pools. The amino acid sequence encoded by the nucleotide sequence in this region is indicated.

Methods: 10^6 λ phage containing human genomic DNA were screened on duplicate filters using the long probes (see Fig. 1) which had been phosphorylated to a specific activity of 10^7 c.p.m. per pmol. Hybridization was at 37 °C in the presence of 30% formamide using 10^7 c.p.m. per filter. Filters were washed in 3×SSC (1×SSC = 0.15 M NaCl, 0.015 M Na-citrate) at 37 °C and exposed to X-ray film. Phage from 300 small areas corresponding to the number and location of positive signals were replated on individual plates and probed with long and short probes (Fig. 1). Short probe hybridization was at room temperature in the presence of 20% formamide and corresponding filters were washed at the same temperature in 5×SSC. DNA from the single isolate which hybridized with both pools of oligomers was cleaved with restriction enzymes and DNA fragments characterized by Southern[40] analysis using the two oligonucleotide pools as probes under the conditions specified above. A 1,200-bp DNA fragment containing the hybridizing region was cloned into phage M13 mp18 RF-DNA and recombinant single-stranded DNA was sequenced using primed DNA synthesis in the presence of dideoxynucleoside triphosphates[21,47].

The remainder of the LHRH precursor consists of a peptide of 56 amino acids, the function of which is unknown. It does not contain any sites for *N*-glycosylation (Asn-X-Thr/Ser) and no homologies were found when the sequence was compared with other known hypothalamically produced precursors to neuroendocrine peptides[34-37]. Interestingly, the C-terminus of this peptide consists of the sequence Lys-Lys-Ile, which may represent an enzymatic cleavage site for further processing. It is likely that the resulting peptide of 53 amino acids is released together with LHRH, possibly to complement the biological function of the decapeptide in ways not yet understood. It might be a carrier protein of LHRH in analogy with neurophysins[34,38] or it could be involved in the release of follicle-stimulating protein (FSH) from pituitary gonadotrophs, a process for which an agent other than LHRH has been invoked[39].

The LHRH precursor produced in placenta and hypothalamus is probably the same, as antisera raised against a synthetic peptide derived from its sequence can be used to stain rat hypothalamic LHRH-producing neurones (H. Phillips *et al.*, in preparation). In addition, Southern analysis[40] of the human genome using the cloned cDNA as a probe did not reveal the presence of related genes (J.P.A. *et al.*, in preparation). The two other hypothalamic releasing factors for which cloned cDNAs exist, namely growth hormone releasing factor and corticotropin releasing factor, are also encoded by single genes[36,37]. However, the molecular weight of 10,000 (10K) for prepro-LHRH as deduced from the cloned cDNA is much smaller than the 28K precursor reported from *in vitro* translation and immunoprecipitation of rat hypothalamic mRNA[41]. There are two possible

Fig. 4 Amino acid and nucleotide sequence of prepro-LHRH and its cDNA as isolated from human placental tissue. Numbers for amino acids appear within the sequence, whereas nucleotide numbers are given on the right-hand side. The nucleotide sequence is that of the longer cDNA clone. The shorter cDNA starts at nucleotide 683 (see horizontal arrow) and nucleotide differences between the two cDNAs (positions 702, 997) are indicated. The overlined ATG indicates an alternative translational initiation codon. The Lys-Arg processing site for the precursor sequence is boxed and the glycine involved in carboxy-terminal amidation is underlined. A second possible processing site at the C-terminus of the precursor protein is shown by a hyphen. Arrows indicate interruptions due to introns in the corresponding genomic DNA sequence (J.P.A. *et al.*, in preparation). The AATAAA polyadenylation signal[27] is underlined.

Methods: Polyadenylated RNA (10 μg) from human placental tissue was converted into double-stranded cDNA using standard procedures[49]. The cDNA was cloned using phage λgt10 as a vector according to published methods[23]. 1.5×10^6 recombinant phage were obtained and screened using a DNA fragment isolated from the genomic clone (Fig. 3) and labelled[50] to a specific activity of 10^8 c.p.m. per μg. Two hybridizing λ clones were isolated and found to contain cDNA inserts of ~1,500 and 800 bp, respectively. These cloned cDNAs were sequenced using single-stranded recombinant M13 DNA as templates for the primed DNA synthesis in the presence of dideoxynucleoside triphosphates[21,47].

explanations for this discrepancy. It can be argued that the protein seen by immunoprecipitation is not the LHRH precursor, especially as the competition by unlabelled LHRH used in the experiments[41] may not be a reliable means of identification. Alternatively, the 28K precursor could give rise to the hypothalamically expressed LHRH, whereas the placenta might produce a smaller protein. If this is the case, different LHRH-encoding genes would be expressed in hypothalamus and placenta, or different sets of exons spliced in a tissue-specific fashion[42] from the same primary gene transcript.

Although the genomic analysis (see above) might be taken to indicate the existence of only one LHRH gene—and its expression in both hypothalamus and placenta—it should be stressed that different genes for LHRH need only be homologous in their DNA encoding the decapeptide. Homology over such a small region might not be detected using cDNA probes, as shown by the related sequences for proopiomelanocortin[15] and preproenkephalin A (ref. 16) and B (ref. 43). Isolation of cDNA coding for hypothalamically-produced LHRH will reveal which of the alternatives outlined above is correct.

We thank Mark Vasser and Kim Dinkelspiel for the synthesis of the oligodeoxynucleotides used in this study, Joel S. Hayflick for his help in the DNA sequence analysis, Drs Karoly Nikolics and Anthony Mason for critically evaluating this manuscript and Jeanne Arch for helping in preparing it.

Developmentally regulated production of platelet-derived growth factor-like molecules

Ronald A. Seifert, Stephen M. Schwartz & Daniel F. Bowen-Pope

Department of Pathology, SM-30, School of Medicine,
University of Washington, Seattle, Washington 98195, USA

Platelet-derived growth factor (PDGF) is thought to mediate the proliferation of smooth muscle cells in injured arteries, and may be involved in the pathogenesis of atherosclerosis[1]. PDGF-like molecules from non-platelet sources may also play a role in the regulation of cell activity in other circumstances. Transformation of cells by a wide range of oncongenic agents appears to activate a cellular gene encoding a PDGF-like molecule[2-6], possibly accounting for the ability of transformed cells to grow without addition of exogenous mitogens[7-12]. We show here that a molecule (PDGF-c) which can compete with ^{125}I-PDGF for binding to PDGF receptors is secreted by cultured rat aortic smooth muscle cells (rASMC) isolated from 13 to 18-day-old rats (pups) but not from three-month-old animals (adults). Thus, production of PDGF-c appears to be developmentally regulated and may be a factor in the more rapid proliferation of rASMC and synthesis of connective tissue components which occurs during growth of the aorta *in vivo*.

Pup rASMC secrete into their culture medium an average of 170 times (Range 77-1,100×) more PDGF-c than do adult rASMC (Table 1). This difference is consistently observed for two separate isolates (pup and adult) of rASMC from each of three different rat strains. Prior adsorption of pup rASMC-conditioned medium with goat anti-PDGF IgG covalently coupled to Sepharose-4B completely abolishes the ability of pup rASMC-conditioned medium to reduce ^{125}I-PDGF binding to human fibroblasts (data not shown), demonstrating that pup rASMC PDGF-c is antigenically related to PDGF. Pup, but not adult, rASMC continue to produce PDGF-c during 20 passages in culture over a period of at least six months. These data suggest that the critical events occurring *in vivo* between the ages of two weeks and three months is not a mere consequence of the passage of time or number of cell divisions. Pup rASMC-conditioned medium is mitogenic for 3T3 fibroblastoid cells (Fig. 1), whereas adult rASMC-conditioned medium is nonmitogenic or only weakly so (data not shown). Stimulation of DNA synthesis by added PDGF or pup rASMC-conditioned medium is, however, completely prevented by simultaneous addition of goat anti-PDGF IgG (Fig. 1). Comparable amounts of non-immune goat IgG have no effect. We conclude from these results that pup rASMC PDGF-c is mitogenic as well as antigenically similar to PDGF.

Table 1 Rate of PDGF-c production by rASMC

Rat strain	Rate of PDGF-c production (ng per equiv.) Pup	Adult
Sprague–Dawley		
Isolate 1	1.13	0.036
Isolate 2	1.09	0.01
Wistar Kyoto		
Isolate 1	1.92	0.002
Isolate 2	2.25	0.004
Spontaneous hypertensive rat		
Isolate 1	3.48	0.003
Isolate 2	0.48	0.006
Average ± *s.d.*	1.73 ± 1.07	0.01 ± 0.013

Aortic smooth muscle cells were placed into culture as described elsewhere[36]. The PDGF-c concentration in media conditioned (Ref. 6 for method) by two different isolates of rASMC obtained from 13- to 18-day-old or 3-month-old rats of three strains (Sprague–Dawley, Wistar Kyoto, and the spontaneously hypertensive rat) was determined by radioreceptor assay[18,37] using volumes of conditioned medium resulting in an approximately 50% decrease in specifically bound ^{125}I-PDGF (radiolabelled as previously described[13,37]). The results were normalized by expressing production rate as ng PDGF-c per equivalent (where an equivalent equals 1 ml medium conditioned by 1×10^6 cells for 48 h). The tabulated values are the averages of at least two, and in most cases three or more, determinations of PDGF-c concentration.

Isolates of pup rASMC possess considerably fewer binding sites for ^{125}I-PDGF compared with adult rASMC; the binding which does occur increases linearly over the ^{125}I-PDGF concentration range tested (Fig. 2). This binding may be to a previously unrecognized PDGF-binding site with a dissociation constant substantially greater than that of the PDGF mitogen receptor. At concentrations of ^{125}I-PDGF near to the apparent dissociation constant of the PDGF mitogen receptor (6.6×10^{-12} M), adult rASMC isolates bind 11-26 times more ^{125}I-PDGF than pup rASMC from the same strain (Fig. 2). We also measured ^{125}I-PDGF binding to human foreskin fibroblasts (6.5×10^4 receptors/cell) and to A431 carcinoma cells (no detectable receptors/cell), for comparison with rASMC (Fig. 2*a*).

PDGF-receptor complexes are rapidly internalized at 37 °C, resulting in a marked reduction in membrane receptors available for binding subsequently added ligand[13-17], a process referred to as down regulation[18,19]. Since pup rASMC secrete PDGF-c, any PDGF receptors produced by these cells may be continuously down regulated by endogenously produced PDGF-c. To examine this possibility, we determined the effect of PDGF and rat pup PDGF-c on the binding properties of test cells (Table 2). Human fibroblasts preincubated at 37 °C with PDGF or pup rASMC-conditioned medium (which contains PDGF-c) retain very few binding sites for ^{125}I-PDGF. The level of ^{125}I-PDGF binding to adult rASMC preincubated with PDGF or pup rASMC-conditioned medium was reduced to levels approaching that of pup rASMC (Table 2). Medium conditioned

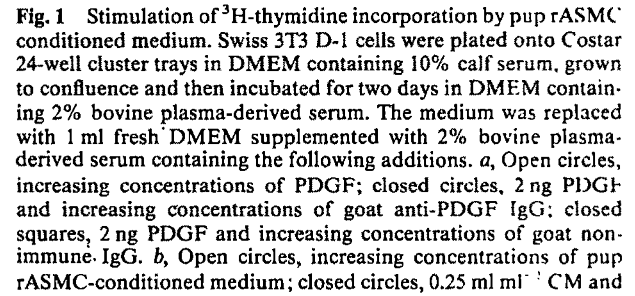

Fig. 1 Stimulation of ^{3}H-thymidine incorporation by pup rASMC conditioned medium. Swiss 3T3 D-1 cells were plated onto Costar 24-well cluster trays in DMEM containing 10% calf serum, grown to confluence and then incubated for two days in DMEM containing 2% bovine plasma-derived serum. The medium was replaced with 1 ml fresh DMEM supplemented with 2% bovine plasma-derived serum containing the following additions. *a*, Open circles, increasing concentrations of PDGF; closed circles, 2 ng PDGF and increasing concentrations of goat anti-PDGF IgG; closed squares, 2 ng PDGF and increasing concentrations of goat non-immune IgG. *b*, Open circles, increasing concentrations of pup rASMC-conditioned medium; closed circles, 0.25 ml ml^{-1} CM and increasing concentrations of goat anti-PDGF IgG closed squares, 0.25 ml ml^{-1} CM and increasing concentrations of goat non-immune IgG [Monospecific antiserum to pure PDGF was prepared in a goat. (Elaine Raines, personal communication). IgG was prepared by sodium sulphate precipitation and DEAE chromatography]. The cells were incubated with test substance for 19 h, 37 °C and then ^{3}H-thymidine incorporation determined as described previously[13]. Results are expressed as the ratio of ^{3}H-thymidine incorporation by cells exposed to test mixtures to incorporation by untreated cells. The plotted values are the means of triplicate determinations from a representative experiment. The pup rASMC-conditioned medium was produced by cells isolated from 16-day-old Sprague-Dawley rats and contained 3.06 ± 0.54 (*s.d.*) ng ml^{-1} PDGF-c. CM, conditioned medium.

Table 2 PDGF receptor expression by rASMC and human fibroblasts after exposure to pup rASMC-conditioned medium or PDGF

Cell type	Test substance (amt per ml)	Specific ^{125}I-PDGF binding (c.p.m. per 10^6 cells)
a Human fibroblasts	0	34,300
	2 ng PDGF	0
	1 ml Pup CM	2,400
	1 ml Adult CM	20,500
b Pup rASMC	0	900
c Adult rASMC	0	5,400
	2 ng PDGF	1,400
	1 ml Pup CM	2,600
	1 ml Adult CM	5,900

Pup rASMC-conditioned medium was obtained from cells isolated from 18-day-old Sprague-Dawley rats and contained 1.12 ng ml^{-1} of PDGF-c. Adult rASMC-conditioned medium was obtained from cells isolated from 3-month-old spontaneously hypertensive rats and contained 0.026 ng ml^{-1} PDGF-c. Human adult foreskin fibroblasts were prepared as for the radioreceptor assay[18,37] and rASMC were plated onto Costar 24-well cluster trays in DMEM containing 20% fetal bovine serum, grown to confluence, then incubated in DMEM containing 2% bovine plasma-derived serum. Two days later the cells were exposed to 1 ml binding medium, 1 ml binding medium containing 2 ng ml^{-1} PDGF, or 1 ml rASMC-conditioned medium supplemented with 0.025 M HEPES, *p*H 7.4 for 4 h, 37 °C. The cells were washed three times with binding rinse and then exposed for 2 h, 4 °C to 1 ml binding medium containing 0.5 ng ml^{-1} ^{125}I-PDGF. Specifically bound radioactivity was determined as described in Fig. 2 legend, and cell counts were obtained from parallel cells treated with binding medium alone. Numbers are the mean of triplicate wells from a representative experiment. Since pup rASMC do not express detectable high affinity receptors for ^{125}I-PDGF (see Fig. 2) they were only examined for their ability to bind ^{125}I-PGDF following exposure of the cells to binding rinse alone. CM, conditioned medium.

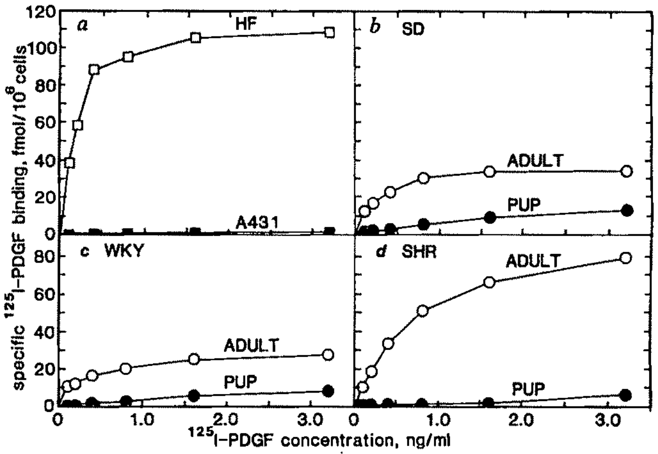

Fig. 2 Specific binding of ^{125}I-PDGF to rASMC. Cells were plated onto 24-well trays in Waymouth's medium containing 10% or 20% bovine serum or in DMEM containing 10% or 20% fetal bovine serum. After cells had grown to near confluence the media were replaced with DMEM supplemented with 2% PDGF-deficient calf serum (CMS-I; see ref. 38) or 2% bovine plasma-derived serum, and assayed for ^{125}I-PDGF binding 2 to 3 days later as previously described[13,37]. Cell counts were obtained from cells treated in a parallel fashion but with binding medium alone and nonspecifically bound c.p.m., determined by exposing cells to ^{125}I-PDGF and an excess of unlabeled, partially-purified PDGF (5-40 μg ml^{-1}, the equivalent of 50 to 400 ng ml^{-1} purified PDGF), was subtracted to determine the amount of specifically bound ^{125}I-PDGF. The plotted values represent the average amount of ^{125}I-PDGF binding to three or more different isolates of rASMC from each age (except for SHR pup, $n = 2$). HF, human fibroblasts; A431, human carcinoma cells; SD, Sprague-Dawley; WKy, Wistar Kyoto; SHR, spontaneously hypertensive rat.

by adult rASMC (which does not contain PDGF-c) had a minimal effect on ^{125}I-PDGF binding to human fibroblasts and no effect on its binding to adult rASMC. Therefore, PDGF-c production by pup rASMC may account for our inability to detect high affinity PDGF receptors on pup rASMC.

We find that adult and pup rASMC express approximately 1.0×10^4 ^{125}I-EGF binding sites per cell with an estimated k_D of 6.7×10^{-10} M (data not shown). There was no detectable difference in the number of EGF receptors expressed by pup and adult rASMC, unlike the PDGF receptor. Pup rASMC-conditioned medium contains no detectable (less than 0.4 ng/ml) EGF-like binding competitor activity as determined by radioreceptor assay (data not shown). The ability of anti-PDGF IgG to completely abolish the stimulation of DNA synthesis by 3T3 cells caused by pup rASMC-conditioned medium (Fig. 1), also indicates that these cells do not secrete biologically significant amounts of non-PDGF-like mitogens for 3T3 cells. Therefore, it appears that the mitogen-related phenotypic differences between adult and pup rASMC are relatively specific for PDGF and do not reflect general differences in mitogen receptor number or in production of growth factors.

A similar phenomenon may occur in human fibroblasts since Clemmons[23] has reported that, in platelet-poor plasma, normal human fetal fibroblasts secrete a factor which enhances their own growth. This does not occur in fibroblasts from three-year-old donors. Pup rASMC, but not adult rASMC, secrete a PDGF-like mitogen and express fewer detectable PDGF receptors. This is consistent with our suggestion that rASMC synthesize the PDGF mitogen receptor at all developmental stages and only pup rASMC synthesize a PDGF-c which provides a constant mitogenic stimulation, resulting in down regulation of their own PDGF receptors. That pup rASMC can respond to the PDGF-c they produce is indicated by the ability of PDGF to stimulate [^{3}H]thymidine incorporation in some, but not all, isolates of pup rASMC (data not shown). Nilsson *et al.*[20] have also reported that rASMC obtained from 5-day-old donors and cultured in serum-free medium respond to added PDGF with increased DNA synthesis and more rapid growth. Thus we suggest that pup rASMC may regulate their growth properties by producing a growth factor (PDGF-c) to which they themselves respond—that is, an autocrine mechanism first proposed to explain the growth properties of transformed cells[21,22].

The basic structure of the rat aorta is already developed at birth[24,25]. From birth until three months of age, however, there is a substantial increase in cell number[26-30] and the amount of connective tissue matrix components[24-27]. PDGF-c could be responsible for these changes since PDGF has been shown to stimulate the growth of cultured smooth muscle cells[13,31-33] and enhance the production of connective tissue components *in vitro*[34,35]. PDGF-c may thus provide an example of autocrine stimulation of growth operating during normal development and which can be inappropriately activated during neoplastic transformation.

We thank Linda Mohai and Karen Tittle for technical assistance and Anna Choi and Jan Fullenwider for typing the manuscript. This research was supported by NIH grants HL 18645 and HL 29873 and a grant from R. J. Reynolds Industries, Inc.

A novel transforming gene in a human malignant melanoma cell line

R. A. Padua, N. Barrass & G. A. Currie

Marie Curie Memorial Foundation, Research Institute, The Chart,
Oxted, Surrey RH8 0TL, UK

Cellular transforming genes can be detected in human tumours by DNA-mediated transfection into NIH 3T3 mouse fibroblasts[1,2]. The activated transforming genes have been, in most cases, members of the *ras* gene family, of which the most frequently found is the c-Ki-*ras* oncogene[3–7] and least frequently the c-Ha-*ras* gene[8–10]. An increasing number of studies has identified the presence of activated N-*ras* (which has no known viral homologue) in human tumour cell lines[11–18]. Furthermore, other transforming genes, distinct from the *ras* gene family, have been reported in B- and T-cell lymphomas[19,20]. The activation of c-Ha-*ras* and N-*ras* has been described in some cell lines derived from cases of human malignant melanoma[21]. Here we describe the presence of transforming activity in the DNA from a human melanoma cell line which shows weak homology with members of the *ras* oncogene family.

High-molecular weight DNA prepared from established melanoma cell lines was used to transform NIH 3T3 cells by the calcium phosphate co-precipitation method[22]. Table 1 shows the results of these transfection assays. The foci observed were collected and grown to confluence, then DNA was extracted and analysed by Southern blotting[23] for human repetitive sequences using Blur 8 (ref. 24), a clone of human *Alu* sequences (Fig. 1), and total human DNA (data not shown). Positive results were obtained for foci derived from lines NKI4, MeWo and Mel Swift. (The Mel Swift line was subsequently found to contain an activated N-*ras* gene and will be reported separately.) DNA from NKI4 and MeWo transformants was further analysed by Southern blotting and hybridization to clones containing v-Ha-*ras* (BS9)[25], v-Ki-*ras* (HiHi-3)[26] and N-*ras* (pAT8.8)[14]. In addition, these DNA samples were blotted and hybridized to probes specific for the following oncogenes: B-*lym*, v-*abl*, v-*sis*, v-*erb*, v-*fes*, v-*fgr*, v-*fms*, v-*fps*, v-*fos*, v-*mos*, v-*myb*, v-*myc*, v-*raf*, v-*src* and v-*yes*. In each case the hybridization pattern obtained was identical to that of normal NIH 3T3 DNA. DNA from serially transformed foci (second cycle transfectants) from NKI4 showed a conserved 16-kilobase (kb) *Eco*RI fragment containing *Alu* sequences (Fig. 1).

Primary and secondary transformants from NKI4 were grown in soft agar (0.3% Noble) and colonies were detected after 2 weeks. Plating efficiencies well in excess of 10% were observed whereas control NIH 3T3 cells had negligible colony-forming efficiencies. Colonies were picked from the soft agar cultures and grown to confluence in liquid medium. DNA was extracted and Southern analysis demonstrated that the *Alu* sequences associated with NIH 3T3 transformation were conserved in cells displaying the anchorage-independent phenotype.

DNA was isolated from a secondary transformant of the NKI4 cell line and enriched for the 16-kb *Eco*RI fragment by size fractionation. This fragment was cloned into λ L47 and one clone was characterized in detail (λNK/16). Hybridization of λNK/16 to clones containing v-Ha-*ras* (BS9), c-Ha-*ras*[10] (pT24-C3), Ki-*ras* (HiHi-3) and N-*ras* (pAT 8.8) under low stringency showed that λNK/16 has some homology with HiHi-3 and c-Ha-*ras* (Fig. 2). Weak hybridization was observed when BS9 was probed with λNK/16 (Fig. 2, lane *b*), but there was clearer evidence of conserved sequences between λNK/16 and BS9 when the λNK/16 clone was probed with BS9 (Fig. 3, lanes *d*, *e*). There was no apparent hybridization of λNK/16 probe to the first exon of N-*ras* (Fig. 2, lane *d*) and λNK/16 failed to hybridize with a probe specific for the first exon of N-*ras* (data not shown). As the first exon of the known *ras* genes is highly

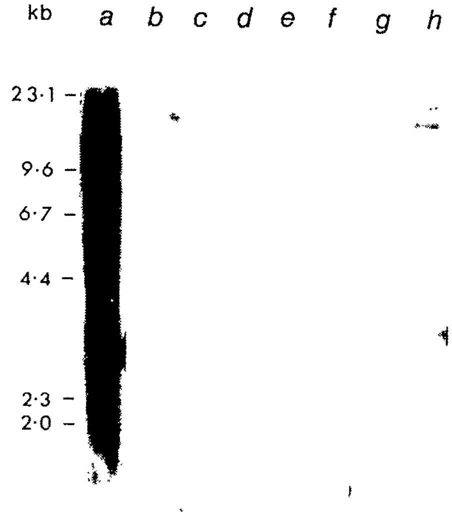

Fig. 1 Detection of human repetitive sequences. 20 μg of high-molecular weight DNA isolated from primary and secondary transformants were digested with *Eco*RI, electrophoresed in horizontal 0.8% agarose gels and blotted onto nitrocellulose filters[23]. The filters were hybridized in stringent conditions[29] to 10^6 c.p.m. ml^{-1} ^{32}P-labelled 0.3-kbp cloned repetitive sequence DNA purified from plasmid Blur 8 (ref. 24; specific activity 2-4×10^8 c.p.m. μg^{-1}). Filters were washed with 0.6×SSC, 0.1% SDS at 60 °C for 1 h. NKI4 transformants: lane *a*, primary focus; lanes *b*-*f*, secondary foci; lane g, NIH 3T3; lane *h*, EJ secondary focus. *Hin*dIII-digested λ cI857 DNAs served as molecular weight markers.

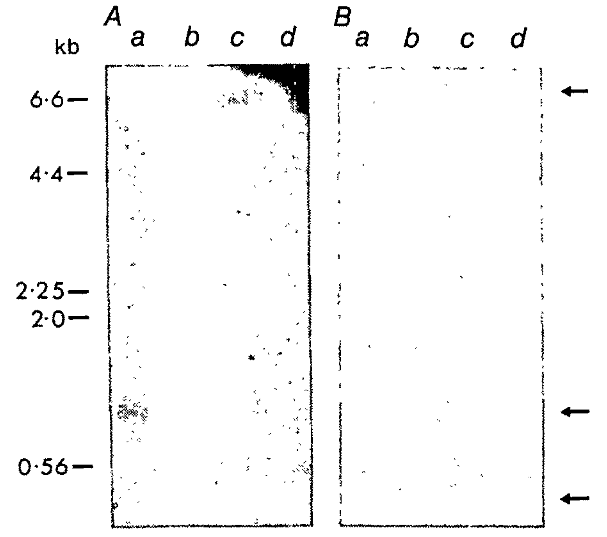

Fig. 2 Hybridization of λNK/16 to members of the *ras* gene family. Lane *a*, v-Ki-*ras* (Hi-Hi 3)[26]; *b*, v-Ha-*ras* (BS9)[25]; *c*, c-Ha-*ras* (pT24-C3)[10]; *d*, N-*ras* (*Pvu*II fragment containing exon 1). Arrows indicate positions of cloned insert DNAs. *Hin*dIII-digested λ *c*1857 DNAs were used as molecular weight markers. 10 μg (per lane) of cloned DNA were analysed by Southern blotting and hybridization to the purified insert of λNK/16 clone under: *A*, low stringency conditions of 30% formamide, 6×SSC, 1×Denhardt's at 42 °C and washed in 2×SSC, 0.1% SDS at 60 °C for 1 h, or *B*, high stringency conditions[23] and washed in 0.1×SSC, 0.1% SDS at 60 °C.

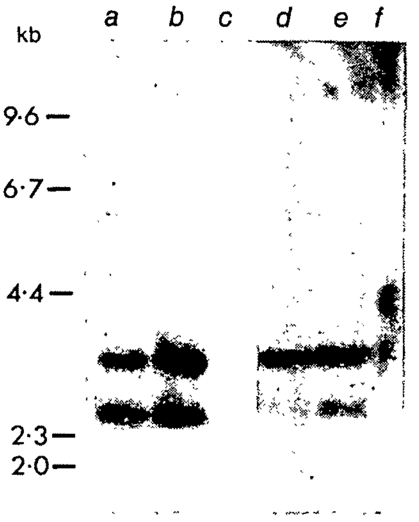

Fig. 3 Detection of human repetitive and *ras*-related sequences in λNK/16. 1 μg of cloned DNA was digested with *Kpn*I and *Pvu*II, electrophoresed on 0.8% agarose gels and blotted onto nitrocellulose filters. Lanes *a–c* were hybridized to Blur 8 in conditions of high stringency as described in Fig. 1 legend. Lanes *d–f* were hybridized to BS9 (v-Ha-*ras*) in conditions of low stringency as described in Fig. 2 legend. Lanes *a*, *d*, λNK/16 insert; *b*, *e*, λNK/16 clone; *c*, *f*, λL47 *Hin*dIII-digested λ *c*1857 DNAs served as molecular weight markers.

conserved, we conclude that λNK/16 must contain divergent sequences which show similarity to the HiHi-3, BS9 and pT24-C3 clones. Hybridization to these clones was lost in high stringency conditions (Fig. 2*B*).

The λNK/16 clone was also hybridized in high stringency conditions to Southern filters containing the plasmid clones of those viral oncogenes mentioned above and to clones of the following cellular and viral oncogenes: v-*ski*, v-*ets*, v-*rel*, c-*sis*, c-*myc*, c-*myb* and c-*mos*. In each case, the plasmid clone had been digested with the restriction endonuclease(s) which separated the oncogene-specific fragment(s) from the remainder of the clone under electrophoresis. No hybridization was observed with the coding sequences of these clones. In conditions of low stringency, faint hybridization was seen with the 1.9-kb pSA17 v-*abl* clone, but this was probably due to the presence of mouse sequences in the clone[27]. The λNK/16 clone detects fragments of 5.5 and 6.5 kb in *Eco*RI-digested human DNA and of 5.0 and 7.0 kb in *Eco*RI-digested dog DNA in high stringency conditions. This suggests that λNK/16 contains conserved sequences. Furthermore, λNK/16 also detects a human transcript of 3.5 kb on Northern blot analysis.

λNK/16 probably contains only part of the gene as it does not cross-hybridize with all of the *ras* gene clones tested. Exon 1 of N-*ras*, for example, is not detected at all. Furthermore,

Table 1 Transforming activity of DNA from melanoma tumours and cell lines

	Transformation frequency, foci per μg DNA (no. foci/no. flasks)		
	1st cycle	2nd cycle	3rd cycle

Fig. 4 Restriction map of λNK/16. Restriction endonuclease sites are as follows: B, *Bam*HI; Bg, *Bgl*II; C, *Cla*I; E, *Eco*RI; K, *Kpn*I; P, *Pst*I; Pv, *Pvu*II; Sm, *Sma*I; Sp, *Sph*I; S, *Sst*I; X, *Xba*I. Underlined enzymes are incompletely mapped. *Hin*dIII and *Sal*I did not cut within the clone. Solid bar indicates regions hybridizing to human DNA. Open bar indicates the region containing mouse-related sequences. Hatched bar indicates region of homology with the v-Ha-*ras* (BS9) probe.

λNK/16 is not active in the NIH 3T3 transfection assay—this lack of biological activity of λNK/16 indicates that the entire activated gene has not been cloned. Comparison of the restriction map of λNK/16 (Fig. 4) with those of the five known human *ras* genes (c-Ha-*ras*1, c-Ha-*ras*2, c-Ki-*ras*1, c-Ki-*ras*2 and N-*ras*[15,28]) indicates that the sequences showing homology with *ras* are likely to be novel. Thus, we have demonstrated a weak homology of λNK/16 with the *ras* gene clones (and not with any other cloned oncogenes), but proof that this gene is a member of the *ras* family must await sequence analysis.

We thank David Hughes, Althea Smallwood, Frederick Rayment, Julia Roberts and Jonathan Fletcher for technical assistance, and Dr Margaret Knowles for help with the biological assays. The cell lines Mel 2a, Mel 57, RPMI 5966, Mel Swift, MeWo and NKI4 were provided by Dr J. Embleton. Our use of NKI4 was by courtesy of Dr Jan de Vries. NIH 3T3 cells were provided by Demetrios Spandidos. Cloned oncogene probes were provided by Drs S. Aaronson, D. Baltimore, M. Bishop, G. Cooper, T. Curran, R. Gallo, A. Hall, J. Neil, D. Lowy, M. Nunn, M. Oskarsson, U. Rapp, C. Sherr, E. Stavnezer, N. Teich and M. Yoshida.

An artefact explains the apparent association of the transferrin receptor with a *ras* gene product

Joe Harford

Laboratory of Biochemistry and Metabolism, National Institute of Arthritis, Diabetes and Digestive and Kidney Diseases, National Institutes of Health, Bethesda, Maryland 20205, USA

There is substantial evidence implicating *ras* genes in a number of human neoplasms[1]. The *ras* genes of several human tumours[2–6] display mutational changes which are likely to be responsible for their transforming activity. Normal cells also express *ras* genes[7], over-expression of which can induce cellular transformation[8]. *ras* genes encode proteins of ~21,000 molecular weight (MW) (p21)[9] that are localized to the inner surface of the plasma membrane[10,11]. Much effort is being focused on the elucidation of the physiological function of *ras*-encoded proteins in normal and transformed cells, concentrating on interactions between p21 and other cellular elements. Recently, Finkel and Cooper[12] reported that p21 in extracts of human bladder carcinoma cells is involved in a molecular complex with the transferrin receptor of these cells. This report aroused considerable interest, particularly as expression of the transferrin receptor has been linked to cell proliferation[13–15]. I present here evidence that the apparent association of p21 and the transferrin receptor is an artefact of the immunoprecipitation technique[12].

Transferrin is an iron-binding protein present in serum at concentrations of 2-4 mg ml^{-1} (ref. 16). The human transferrin receptor can be solubilized in buffers containing non-ionic detergents with the retention of transferrin-binding activity[15,17,18] and the receptor has been purified by affinity chromatography on Sepharose to which transferrin was covalently linked[19]. When immune serum is used for coating the staphylococcal protein A-Sepharose (Pharmacia) to be used in immunoprecipitation, I observe that serum proteins other than IgG can become associated nonspecifically with the resin. Notably, some transferrin remains with the protein A-Sepharose even after extensive washing with buffers containing Triton X-100. When such coated and washed resin is boiled in sample buffer for SDS-polyacrylamide gel electrophoresis, the released proteins revealed by silver staining of the gel included albumin and transferrin in addition to the predominant heavy and light chains of IgG (data not shown). Polypeptides having the molecular weights of albumin and transferin are not observed when uncoated protein A-Sepharose is similarly boiled and analysed. Thus, protein

A-Sepharose coated with immune serum is in effect an affinity column for the transferrin receptor.

The observations that led Finkel and Cooper[12] to conclude that the transferrin receptor is associated with the *ras* gene product are consistent with inadvertent affinity purification of the transferrin receptor during p21 immunoprecipitation. To test this hypothesis, protein A-Sepharose coated in various ways was added in the absence of additional antibodies to a lysate of ^{35}S-methionine-labelled T24 bladder carcinoma cells. No band corresponding to the 90,000-MW transferrin receptor subunit was found to be associated with uncoated protein A-Sepharose (Fig. 1, lane *b*). This lysate does contain labelled transferrin receptor, demonstrated by inclusion of a monoclonal antibody (B3/25, Boehringer Mannheim) which recognizes the transferrin receptor (Fig. 1, lane *a*). B3/25 is bound by protein A and thus no coating of the resin is needed for immunoprecipitation of the transferrin receptor. Precoating of the protein A-Sepharose with an IgG fraction of rabbit anti-rat IgG (Cappel) results in an increase in antibody-independent association of several radioactive polypeptides from the cell lysate; most notably a band appears having the molecular weight of the transferrin receptor subunit (Fig. 1, lane *c*). This is most likely to occur as a result of transferrin present in the IgG fraction used to coat this resin. Indeed, when whole rabbit serum against rat IgG (Cappel) is used for coating the protein A-Sepharose, a significant increase is seen in the amount of receptor bound by the resin (Fig. 1, lane *d*), reflecting the higher transferrin content of the coating substance. The inclusion of rat anti-*ras* monoclonal, Y13-238 (a gift of M. Furth) results in the immunospecific binding of radiolabelled p21 from the lysate (Fig. 1, lane *e*), but no increase in the amount of transferrin receptor associated with the resin. Finkel and Cooper[12] used normal rat serum as a negative control for the rat anti-*ras* monoclonal antibodies. Therefore, the effect of normal rat serum was examined in the present study. When 20 μl of normal rat serum are used in place of the anti-*ras* antibody, not only is p21 no longer present but the transferrin receptor also disappears (Fig. 1, lane *f*). This latter effect is probably the result of transferrin in the normal rat serum. This rat serum transferrin seems able to compete with the rabbit transferrin on the coated resin, preventing the affinity binding of the transferrin receptor. In support of this contention, human diferric transferrin (100 μg ml^{-1}) also eliminates the receptor band when added to serum-coated protein A-Sepharose in the absence of additional antibodies (Fig. 1, lane *h*). It has long been recognized that extensive species cross-reactivity exists in the interaction of transferrin and its receptor[20,21]. The addition of anti-*ras* monoclonal together with 20 μl of normal rat serum yields the expected result; p21 is immunoprecipitated by the anti-*ras*, but the transferrin receptor was prevented from interacting with the serum-coated protein A-Sepharose by the transferrin in the normal rat serum (Fig. 1, lane *g*). To demonstrate conclusively that the T24 lysate contained active transferrin receptor capable of being affinity purified, a portion of the labelled lysate is exposed to Sepharose covalently linked with human diferric transferrin (a gift of G. Ashwell). After washing and boiling the transferrin-Sepharose in analogy to the immunoprecipitations, the major polypeptide seen on the SDS gel is the 90,000-MW transferrin receptor subunit (Fig. 1, lane *i*). Addition of transferrin to the lysate prevents this intentional affinity chromatography of the receptor on transferrin-Sepharose (Fig. 1, lane *j*).

All our observations are consistent with the absence of any direct association between p21 and the transferrin receptor. When anti-*ras* is added in the absence of normal rat serum, p21 is precipitated with no increase in the amount of resin-associated transferrin receptor (compare Fig. 1, lanes *d* and *e*). Likewise, when anti-*ras* is added in the presence of normal rat serum, p21 is precipitated but there is no *ras*-specific precipitation of the transferrin receptor (compare lanes *f* and *g*). Unfortunately, Finkel and Cooper[12] used conditions analogous to lane *f* as a negative control for an anti-*ras* immunoprecipitation analogous

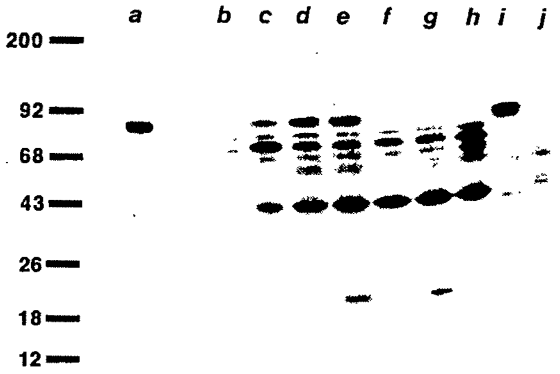

Fig. 1 Electrophoretic analysis of samples from the lysate of ^{35}S-methionine-labelled T24 cells. Lane *a*, material bound by an anti-transferrin receptor monoclonal antibody using uncoated protein A-Sepharose; lane *b*, material bound by uncoated protein A-Sepharose alone; lane *c*, material bound protein A-Sepharose coated with an IgG fraction of rabbit anti-rat immunoglobulin serum; lane *d*, material bound by protein A-Sepharose coated with rabbit anti-rat immunoglobulin serum; lane *e*, anti-*ras* monoclonal antibody added to lane *d* conditions; lane *f*, normal rat serum added to lane *d* conditions; lane *g*, anti-*ras* monoclonal antibody plus normal rat serum added to lane *d* conditions; lane *h*, transferrin added to lane *d* conditions; lane *l*, material bound by transferrin-Sepharose; lane *j*, transferrin added to lane *l* conditions. Numbers to the left of the gel represent molecular weights × 10^{-3} of marker polypeptides.

Methods: Human bladder carcinoma cells (T24) at 75% confluence were labelled in 100-mm culture dishes for 18 h by incubation with 400 μCi ml^{-1} ^{35}S-methionine (Amersham) in 2.5 ml RPMI 1640 medium containing 10% fetal bovine serum and 10% of the normal amount of methionine. The labelled cells were washed twice with 10 ml ice-cold phosphate-buffered saline and then scraped into cell lysis buffer (2 ml per dish) consisting of 0.125 M NaCl, 1 mM $CaCl_2$, 1 mM $MgCl_2$, 1% Triton X-100, 3 trypsin inhibitory units per ml aprotinin (Calbiochem), 0.2 M Tris-HCl, *p*H 7.4. The cells were then homogenized with 20 strokes of a Dounce homoginizer (Kontis, pestle B) and clarified by centrifugation at 30,000*g* for 20 min. The resultant supernatant fluid was used for immunoprecipitations and affinity chromatography. Each sample contained 5×10^7 trichloroacetic acid-precipitable c.p.m. in a volume of 500 μl. All reactions were performed in 1.5-ml Eppendorf tubes. Lysates were first incubated for 1 h at 4 °C with 25 μl of staphylococcal protein A-Sepharose beads (as a 25% suspension in lysis buffer) that had been coated with rabbit anti-rat immunoglobulin serum (Cappel) and washed extensively (5 times, 15 volumes) with phosphate-buffered saline. This resin was removed by centrifugation and the preadsorbed lysate incubated for 1.5 h at 4 °C with no addition (lanes *b*, *c*, *d*, *i*) or after addition of 10 μl anti-transferrin receptor monoclonal antibody B3/25 (lane *a*), 2 μl anti-*ras* monoclonal Y13-238 (lane *e*), 20 μl normal rat serum (lane *f*), 2 μl of anti-*ras* monoclonal Y13-238 plus 20 μl normal rat serum (lane *g*), or 100 μg ml^{-1} human diferric transferrin (lanes *h*, *j*). Following these incubations, 25 μl (as a 25% suspension in lysis buffer) of either uncoated protein A-Sepharose (lanes *a*, *b*) or protein A-Sepharose previously coated with an IgG fraction of rabbit anti-rat immunoglobulin serum (lane *c*), protein A-Sepharose previously coated with rabbit anti-rat immunoglobulin serum (lanes *d*-*h*), or transferrin-Sepharose (3 mg human diferric transferrin per ml resin) (lanes *i*, *j*) were added and the Eppendorf tubes tumbled for 1.5 h at 4 °C. The resins were washed by seven cycles of brief centrifugation and resuspension in 1 ml of cell lysis buffer. The final pellet was boiled in the sample buffer and analysed on 10-20% linear gradient polyacrylamide slab gel using the buffer system of Laemmli[22]. The gel was treated with 1 M sodium salicylate for fluorography before drying and exposure to Kodak X-ray film at −70 °C.

to lane *e*. When these lanes are compared in isolation, the presence of the transferrin receptor in the immunoprecipitate appears to be *ras*-specific.

Transferrin-laden normal rat serum is clearly an inappropriate control for monoclonal antibodies collected by salt precipitation from ascites fluid or from culture fluid of hybridoma cells grown in medium with or without 10% fetal bovine serum[11]. Finkel and Cooper[12] also observed that transferrin added to the lysate eliminated the transferrin receptor band from anti-*ras* immune precipitates and proposed a transferrin-mediated conformational change in the receptor that disrupted the interaction with p21. They also suggested that a disruption of the p21-receptor complex by an anti-transferrin receptor monoclonal antibody was responsible for the fact that p21 was not co-precipitated by anti-receptor. The effect of transferrin and the asymmetrical co-precipitation are both explained more simply by the inadvertent affinity chromatography of the receptor demonstrated here. Loss of co-precipitation of the receptor on 'exhaustive precipitation' with anti-*ras*[12] may be due to the difference in the nature of the binding of the transferrin receptor to the resin in the absence and presence of anti-receptor antibodies. Only biologically active receptor can be bound by virtue of its affinity for the transferrin present on coated protein A-Sepharose. No such dependence on activity applies, however, in the binding of receptor by anti-receptor antibody. Thus, any loss of biological receptor activity during extraction or handling would result in transferrin receptor that could no longer become associated with coated protein A-Sepharose by affinity chromatography but which would still be precipitated with anti-receptor antibody. Partial inactivation of the receptor may also account for the high variability (5-50%) in the molar amounts of transferrin receptor apparently co-precipitated by anti-*ras*[12]. It is unsurprising that several anti-*ras* monoclonal antibodies apparently co-precipitated the transferrin receptor[12] because the association of the receptor with the coated proteinA-Sepharose is independent of the presence of the anti-*ras* (Fig. 1, lanes *b-d*). Using the methodologies of Finkel and Cooper[12] with normal rat serum as a control, addition of other monoclonal antibodies against any protein in the lysate would yield results suggesting that the transferrin receptor is co-precipitated specifically.

The results of Finkel and Cooper[12] have been reproduced here but additional controls support the lack of any molecular complex between p21 and the transferrin receptor. Although the 90,000 MW polypeptide observed[12] is the transferrin receptor, its presence in immunoprecipitates is demonstrated to be independent of anti-*ras*. I have shown here that it is due to inadvertent affinity chromatography resulting from the presence of transferrin on the coated protein A-Sepharose used in immunoprecipitation.

I thank E. Chang for her gift of T24 cells, M. Furth for the anti-*ras* monoclonal antibody, G. Ashwell for preparation of transferrin-Sepharose, and G. Ashwell, E. Chang and R. D. Klausner for discussions and comments.

FINKEL AND COOPER COMMENT—Since learning of the above results we have repeated our experiments with additional controls. We concur with Harford that our findings are explained by the artefact he describes and, therefore, do not indicate an interaction between transferrin receptor and *ras* proteins.

In vertebrates all iron is taken up via the carrier protein transferrin[1]. The carrier first binds its receptor and the receptor–ligand complex is then internalized via coated pits[2–4]. The transferrin receptor is a transmembrane glycoprotein (apparent molecular weight (MW) 180,000) composed of two disulphide-bonded subunits (each of apparent MW 90,000)[1,5,6]. It contains three N-linked glycan units and is post-translationally modified with both phosphate and fatty acyl groups[5,7]. Here we have determined the nucleotide sequence of the coding region of the human transferrin receptor mRNA and from this deduced the amino acid sequence of the protein. The receptor does not contain an N-terminal signal peptide but there is a membrane-spanning segment 62 amino acids from the N-terminus. It therefore has a somewhat unusual configuration with a small N-terminal cytoplasmic domain and a C-terminal extracellular domain of 672 amino acids.

The clone pTR48 contains a 2-kilobase (kb) cDNA insert derived from the human transferrin mRNA[8]. Using this clone as a probe, a set of five overlapping cDNA clones was isolated containing, in total, 5 kb of sequence derived from the human transferrin receptor mRNA (Fig. 1). The mRNA is slightly over 5 kb long (ref. 9 and C.S., unpublished) thus this set of clones probably spans most of the length of the mRNA. We have used primer extension (Fig. 2) to show that the insert in clone pTR36 terminates only 20(±2) nucleotides from the 5′ end of the mRNA. The nucleotide sequence of the inserts in the set of cDNA clones was determined and is presented in Fig. 3. There is an open reading frame which extends from nucleotide 33 to nucleotide 2,544. The first available initiation codon in this reading frame is at position 264 and translation using this codon

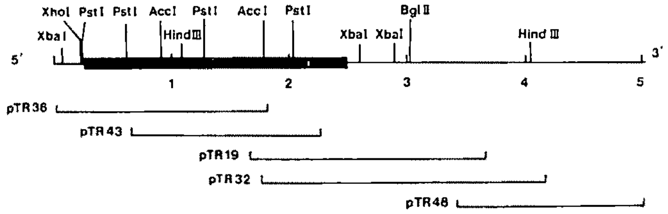

Fig. 1 Molecular cloning of human transferrin receptor cDNA sequences. The cDNA clone pTR48 was prepared using the orthodox 'hairpin cleavage' technique and shown by hybrid selection to contain human transferrin receptor sequences[8]. The complete nucleotide sequence of the cDNA clone was established using the dideoxy technique and the orientation of the insert was deduced by hybridization of cDNA to single-stranded DNA from one of the recombinant clones used in establishing the sequence. Analysis of the transferrin receptor mRNA by Northern transfer (data not shown) indicated that it was ~5 kb long, and the nucleotide sequence of the cDNA insert showed that it was derived from a noncoding region of the mRNA. An oligomer containing 18 nucleotides of sequence from very near the 5' end of the insert in pTR48 (given by Dr I. Stabinsky) was used to prime cDNA synthesis with ~5 μg of immune-enriched mRNA from MOLT-4 cells. This mRNA was derived from immune-selected polysomes in which transferrin receptor mRNA was estimated to constitute between 5 and 10% (by mass) of the mRNA population. Double-stranded (ds) DNA was prepared from the RNA-DNA hybrid using RNase H and the DNA polymerase I holoenzyme exactly as described by Gubler and Hoffman[21]. dsDNA >1,600 nucleotides long was selected by agarose gel electrophoresis and inserted into a pBR322-based vector, p2732K (J. Monahan, unpublished) by homopolymer tailing. The library of ~10,000 cDNA clones was screened by hybridization with a restriction fragment from near the 5' end of the insert in pTR48. Approximately 500 clones gave a positive signal and clones pTR19 and pTR32 were purified and used to screen for cDNA clones containing sequences more proximal to the 5' end of the mRNA. The entire set of overlapping cDNA clones shown was isolated in this way and yielded the indicated restriction map for a DNA copy of the human transferrin receptor mRNA. The map agrees precisely with that published recently by Kühn *et al.*[9]. Based on our estimate of the size of the mRNA, it seemed likely that the clone pTR36 would contain sequences from very near the 5' end of the mRNA and this was confirmed by primer extension (Fig. 2). (Given the method of construction of the clones, all of them might be expected to share a common 3' terminus—that is, the sequence of the oligonucleotide primer. However, only clone pTR32 has a terminus in the expected position. We believe this may be due to random priming because a very large excess of oligomer was used in the cDNA synthesis. This will not affect our sequence analysis because the region of overlap between clones is large and sequences across the termini were in each case established independently from another clone.)

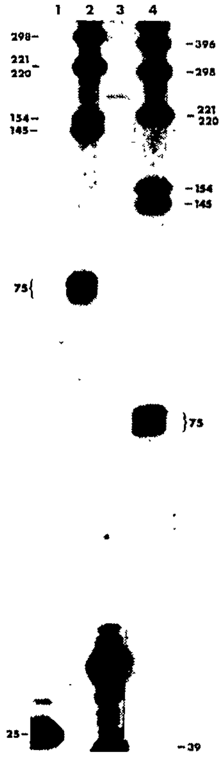

Fig. 2 Analysis of the 5' terminus of the human transferrin receptor mRNA by primer extension. The conditions for the hybridization of the DNA primers to the RNAs and the extension reactions were as described by Devine *et al.*[22] except that the temperature of the hybridization step was 55 °C. The first primer used was a single-stranded 25-nucleotide *Hha*I-*Xba*I fragment derived from within the 5'-noncoding region of the pTR36 transferrin receptor cDNA clone (Fig. 1) labelled at its 5' end with [γ-^{32}P]-ATP and T4 polynucleotide kinase. Lane 1 shows an extension product of 64±2 nucleotides obtained with this primer and an RNA preparation immune-selected with a preparation of anti-transferrin receptor antibody as described by Schneider *et al.*[8]. Identical extension products were obtained using total placental RNA or size-selected (≥5 kb) placental RNA preparations (data not shown). The second primer was a single-stranded 39-nucleotide *Xho*I-*Hae*III fragment derived from the beginning of the coding region of the transferrin receptor cDNA clone (Fig. 1), similarly labelled at its 5' terminus with [γ^{32}-P]-ATP and T4 polynucleotide kinase. Lane 3 shows the extension product of 250±2 nucleotides obtained with this primer and a size-selected (≥5 kb) total placental RNA preparation. Identical extension products were obtained with immune-selected RNA or total placental RNA (data not shown). The size markers in lane 2 were loaded at the same time as the sample in lane 1. The size markers in lane 4 were loaded at the same time as the samples in lane 3. The lengths of the extended products obtained independently with these two primers demonstrate that the start of the human transferrin receptor mRNA is no more than 20±2 nucleotides upstream from the start of the cloned cDNA.

generates a polypeptide 760 amino acids long. The deduced molecular weight is in very good agreement with that predicted by translation of the mRNA[8,10] and the position of the presumptive transmembrane segment is precisely that expected (see below). Confirmation that this is the correct reading frame is provided by the amino acid sequence of two tryptic peptides (J. Downward, G. Scrace, R. Sutherland, M. Greaves and M. Waterfield, unpublished data) which are found in our predicted amino acid sequence at the positions indicated in Fig. 3 legend. The 5'-noncoding region of the mRNA is therefore somewhat longer than average (280±2 nucleotides); it is also a little unusual in that there is an ATG trinucleotide upstream of the initiation codon. There are, however, precedents for both these features (reviewed in ref. 11) and the complete concordance with the expected protein structure suggests strongly that we have identified the correct N-terminus.

The 3'-noncoding region is also much longer than that of the average eukaryotic mRNA. We cannot determine the precise length of this region because pTR48, the 3'-proximal clone, does not contain sequences derived from the poly(A) tail. It must, however, terminate very near to the end of the mRNA because the total length of the established nucleotide sequence closely approximates the length of the mRNA. Hence, the 3' noncoding region is >2,466 nucleotides long. Again, this is not without precedent and it is intriguing that the epidermal growth factor (EGF) receptor also displays such a feature[12]. It is also interesting that the 3'-noncoding region contains several AATAAA sequence elements which are not used (Fig. 3).

Inspection of the receptor's predicted primary sequence reveals a stretch of 26 predominantly nonpolar amino acids with a sequence of nine hydrophobic residues in the centre (residues 63–88). When a hydropathicity plot (see Fig. 3 legend) was used to predict hydrophilic and membrane-embedded regions, this segment was the only convincing potential transmembrane segment. It would span, in an α-helical conformation, the 40 Å nonpolar part of the lipid bilayer (Fig. 4). The sequence, however, resides at the N-terminal end of the protein; no hydrophobic stretch is apparent at the C-terminal end. As the majority of the receptor is located at the external face of the bilayer, the receptor must be oriented with its N-terminus on the cytoplasmic side; this is in contrast to most membrane proteins which span the membrane close to the carboxy-terminus, exposing it on the cytoplasmic side (for review see ref. 13). A similar orientation has, however, also been found for several glycoproteins including the chicken asialoglycoprotein receptor, human erythrocyte band 3 protein and the murine and human Ia-associated invariant chain[14-17]. The sequence of the putative transmembrane domain of the transferrin receptor permits multiple interactions within the lipid bilayer, as several residues are capable of forming hydrogen bonds. Also, a cysteine residue, which may

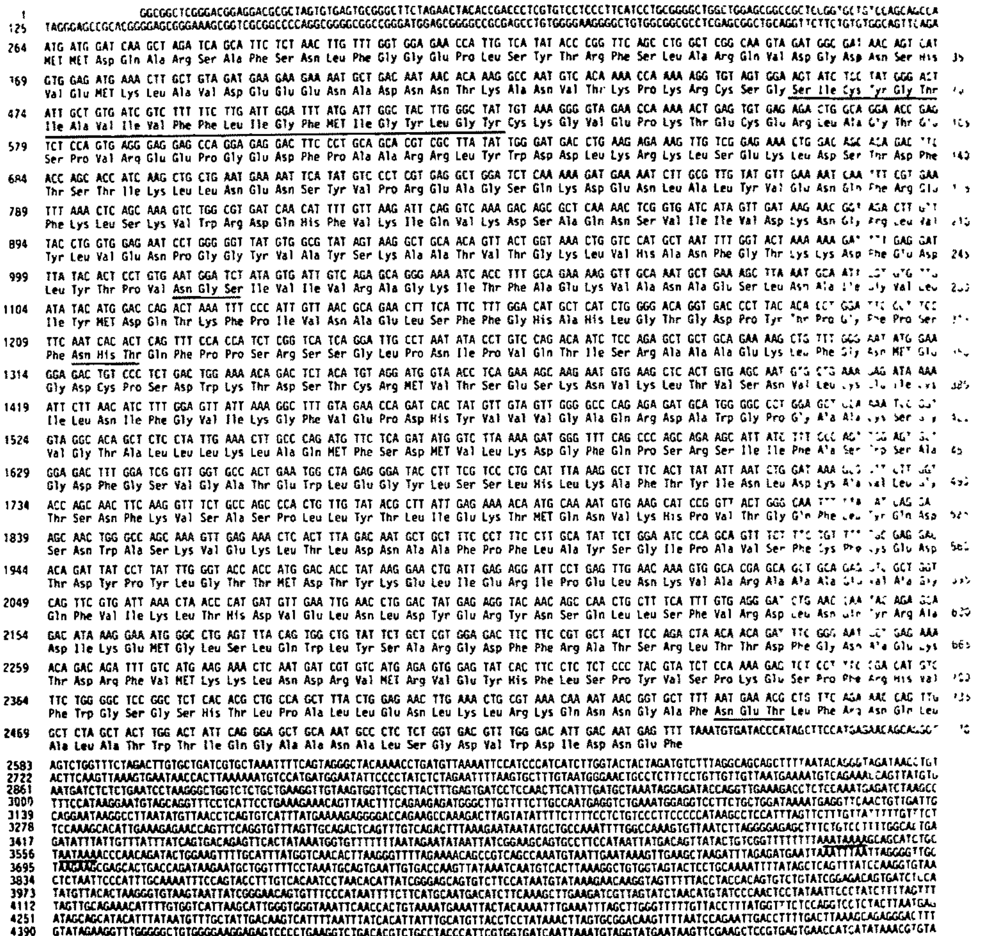

Fig. 3 Nucleotide sequence of the cDNA clones. The entire nucleotide sequence was determined using the dideoxy method of Sanger[27] but the sequence around the 5′-proximal *Xba*I site was confirmed using the chemical procedure of Maxam and Gilbert[28]. This was considered necessary because of difficulty in reading the DNA sequence near the homopolymer tails when using the synthetic procedure. Approximately half the sequence was determined from randomly sheared fragments of DNA inserted into the M13 mp8 vector[23] or the pEMBL vector[24], the remainder of the sequence was determined from ordered deletion series which were generated by random DNase I cleavage and re-circularization. Two procedures were used, one involving the addition of restriction enzyme linkers (D. Ish-Horowicz, personal communication) and the other involving blunt end-ligation to the *Sma*I site in pEMBL8+. The entire sequence of the 5′-noncoding region and that of the coding region was determined in both strands and the majority of the sequence of the 3′-noncoding region was also determined in both strands. The sequence of each nucleotide was determined on average 4.3 times. Note the presence of stop codons in all three frames at positions 24, 30 and 43. The ATG indicated is the first in-frame initiation codon downstream of the stop codon at nucleotide 30 and several lines of evidence (see text) suggest this to be the correct N-terminus. Confirmation that this is the correct reading frame derives from the sequence of two tryptic peptides: Ser-Ser-Gly-Leu-Pro-Asn-Ile-Pro-Val-Gln starting at position 326, and Arg-Arg-Leu-Tyr-Trp-Asp-Leu-Lys starting at position 121. The transmembrane segment (see text) between amino acids 63 and 88 is underlined, as are the positions of the three extracellular glycosylation sites (see text) at amino acids 251, 317 and 727, and the two unused AATAAA elements. A hydropathicity plot was performed on the predicted polypeptide sequence using a method similar to that of Kyte and Doolittle (ref. 25 and M. Green, personal communication). The protein sequence was compared with all proteins in the National Biomedical Research Foundation database using the search program of Wilbur and Lipmann[26]. The parameters used in the data base search were *k*-tuple length = 3, window size = 20, gap penalty = 2. The length-corrected scores for the degree of homology with the EGF precursor and with the chicken transferrin precursor were 4.0E and 3.3E, respectively. A copy of this sequence has been placed in the EMBL data base.

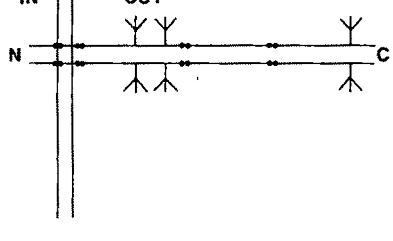

Fig. 4 Proposed structure and membrane orientation of the human transferrin receptor. The receptor is depicted as spanning the plasma membrane close to its N-terminal end, exposing it in the cytoplasm. It contains three glycan units linked to asparagine. The positions of the cysteine residues (●) are indicated.

act as the site of fatty acylation via a thioester bond[18], is present within the bilayer sequence. Since the receptor exists as a dimer in the plasma membrane, self-interactions of the transmembrane segments within the lipid bilayer could help to stabilize the dimer structure; alternatively, they could contribute to associations with other proteins which might be important in receptor function.

The putative transbilayer sequence is preceded (at the N-terminal end) by a cluster of basic residues (Lys-Pro-Lys-Arg). This sequence is found on the cytoplasmic side of the transmembrane segments of virtually all membrane glycoproteins thus far characterized; it has been referred to as a stop-transfer sequence and may interact with the polar phospholipid headgroups[19].

The cytoplasmic domain comprises 62 amino acids and contains four serine residues which can act as acceptors for phosphate modification. This domain is large compared with those of other membrane proteins (3 to ~35 residues long)[13]. However, it is considerably shorter than the corresponding domain of the human EGF receptor, which comprises 542 amino acids[12].

The extracellular domain, which contains the transferrin binding site, comprises 648 amino acids. This domain contains three of the five possible sites for asparagine-linked glycosylation (Asn-X-Ser/Thr). As endoglycosidase digestion experiments have indicated that the receptor contains three N-linked glycan units, all three of these asparagines must be glycosylated.

Eight cysteine residues are distributed throughout the transferrin receptor sequence. Four cysteines are found in the region of the transbilayer peptide; two flank the peptide, one resides within the putative transbilayer sequence, and one is located close to the bilayer on the extracellular side. The remaining cysteines are present in two clusters in the extracellular domain (Fig. 4). It is unknown whether any of these cysteine residues form intrachain disulphide bridges. However, at least one must form the interchain disulphide bond(s) between the two 90,000-MW receptor subunits. Protein biochemical data suggest that the intersubunit disulphide bond(s) must lie close to the cell membrane, as trypsin treatment releases a non-disulphide-linked, 70,000-MW fragment from the cell surface[5]. It is unlikely that the cysteine (residue 62) on the cytoplasmic domain is disulphide-bonded due to the strong reducing environment of the cytoplasm. The cluster of three cysteines close to or in the bilayer are, therefore, the most likely candidates for making an interchain disulphide bond.

The amino-terminus of the transferrin receptor contains no obvious signal sequence. This observation is consistent with *in vitro* translation experiments in which the size of the primary translation product is indistinguishable from that of the endoglycosidase H-treated polypeptide synthesized in the presence of microsomes[10]. The lack of an N-terminal cleavable signal sequence is not unprecedented. No such signal sequence has been identified in the Ia-associated invariant polypeptide, which also has the reverse orientation in the plasma membrane[17]. Similarly, the secreted glycoprotein ovalbumin has been shown to contain an internal signal sequence[20]. It is possible that the transbilayer sequence of the human transferrin receptor performs the dual function of acting as a signal sequence and of anchoring the protein in the plasma membrane.

When the amino acid sequence of the transferrin receptor was used in a search of the Dayhoff data base, no strong homology with any known protein was revealed. There is some homology with the EGF precursor and with the chicken transferrin precursor, but the degree of homology is very low (see Fig. 3 legend). Similarly, a search of a more specialized data base containing a comprehensive collection of oncogene sequences (G. Scrace, personal communication) revealed no strong homologies.

We thank Hiro Mahbubani for technical assistance, Michael Green for performing secondary structure analysis of the protein, and I. Stabinsky for providing the synthetic oligonucleotide described in the text. We also thank G. Scrace, J. Downward, R. Sutherland, M. Greaves and M. Waterfield for allowing us access to protein sequence data in advance of publication, and Rita Harris and Brenda Marriott for their help in preparing the manuscript. C.S. is on leave of absence from the Institute of Biochemistry, University of Trieste, Trieste 34127, Italy.

Three-dimensional structure of an antigenic mutant of the influenza virus haemagglutinin

M. Knossow*‡, R. S. Daniels†, A. R. Douglas†, J. J. Skehel† & D. C. Wiley*

Antigenic variation in the haemagglutinin (HA) glycoprotein of influenza virus is associated with recurrent epidemics of respiratory disease in man (for review see ref. 1). We have examined the size of structural changes necessary to alter the antigenicity of HA by determining the three-dimensional structure of the HA from an antigenic mutant containing a single amino acid substitution which was selected by growth of virus in the presence of monoclonal antibodies. Here we present evidence that the simple addition of an amino acid side chain which results in only minor local distortions of the structure of the HA is sufficient structural alteration for a virus to escape neutralization by a monoclonal antibody. Our results also demonstrate that single amino acid substitutions can cause only local changes in the HA structure, verifying the assumption made in several studies to locate antigenic sites on the HA[2–5] and other molecules[6,7], and indicate that proposals[8,9] of large conformational changes to account for variations in HA antigenicity are unnecessary in this case. The structure of the variant antigen has independently been successfully predicted (M. Karplus, personal communication).

An antigenic variant, V3a, was selected by growing the parent (X31) virus[10] in the presence of a neutralizing monoclonal antibody, HC3a, as described previously[11,12]. Table 1 shows that while haemagglutination by the parent virus is inhibited by HC3a ascitic fluid at a dilution of 1:12,800, the variant virus V3a is not inhibited at a 1:100 dilution of the fluid. A similar result was obtained in enzyme-linked immunosorbent antibody binding assays, in which parent virus and V3a mutant virus bound antibodies at ascitic fluid dilutions of 1:100,000 and 1:100, respectively.

The amino acid sequence of the entire V3a HA was determined by sequencing the viral RNA using methods described previously[13,17,18]; only one nucleotide change was observed, G to A, at nucleotide 514 which, when translated into amino acids, established that V3a has an aspartic acid at position 146 in the HA1 polypeptide instead of the glycine in the parental sequence[19].

Isomorphous crystals of V3a were grown under conditions in which the X31 HA crystallizes[14]. (This has been observed for all of four single amino acid variants tested to date.) We collected 76,840 unique X-ray reflections to 3.0 Å resolution on 1° oscillation photographs recorded at 4 °C by methods described previously[15]. Partially recorded reflections (≥50%) were included in the data set after adjustment by the post-refinement pro-

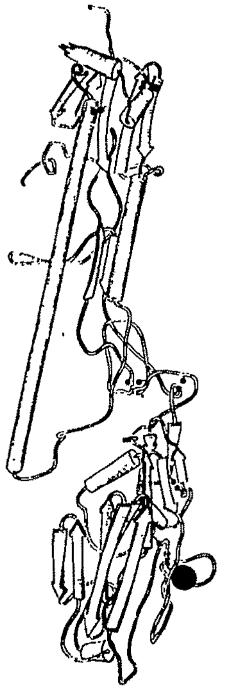

Fig. 1 A schematic diagram of a monomer of the haemagglutinin from the 1968 Hong Kong influenza virus[15], showing the location of the single mutation, Gly to Asp 146.

cedure[16]. The symmetry R factor (see Fig. 2 legend) on fully recorded reflections is 0.11 and on all reflections more than half recorded, 0.14. The parent and variant structure factors were scaled together using a Wilson statistics curve (R scale $= (F_{\mathrm{obs\,V3}} - F_{\mathrm{obs\,X31}})/(F_{\mathrm{obs\,X31}}) = 0.161$) and a difference Fourier was calculated to 3 Å resolution using phases from the refined model (see Fig. 2 legend for details).

The difference Fourier averaged about the molecular 3-fold axis shows nine peaks above the 5σ level. The largest peak is 12σ and is at the location expected for an aspartic acid side chain if it were added to Gly 146 (Fig. 2*b*); the next highest peak is $<6\sigma$. Similar results with fewer noise peaks were observed on a difference Fourier calculated with a shell of data from 10 to 6 Å resolution.

The coordinates of the aspartic acid were obtained from model building on a $2F_0 - F_c$ map after refining native coordinates against V3a data. The O^{δ} of the carboxylate of Asp 146 appears within 3.0 Å of the N^{ε} of Arg 141, forming an apparent hydrogen bond. No other distortion of the external loop (amino acids 139–147) or of other features of the protein are observed, with the exception of a small (less than 1 Å) adjustment in the position of the side chain of arginine 141, presumably to accommodate the hydrogen bonding geometry required by the aspartic acid.

The structure of the variant HA suggests two possible mechanisms for the decreased affinity of the monoclonal antibody for the mutant HA: (1) The difference in the properties (shape, polarity and/or charge) of the aspartic acid and glycine side chains may directly affect the binding affinity. (2) The aspartic acid 146–arginine 141 interaction may stabilize the local structure of the site to which the monoclonal antibody binds, which would decrease the binding affinity if the antibody needed to locally distort or denature the site for tight binding. The former possibility corresponds to the classical 'static' view of an antibody–antigen complex, while the latter would apply if the free energy decrease on binding to a distorted site were greater than that required to distort the site. Present knowledge about the state of an antigen when 'seen' by immunogenic lymphocytes during the generation of an immune response and about the structure of an antigen–antibody complex leaves both possibilities feasible. In the case of V3a, the electrostatic charge of the Asp side chain would lead to unfavourable charge interactions (the burying of an unpaired charge) in complexes with antibodies against the parent (Gly).

Although multiple amino acid substitutions in the HA appear to be necessary for a virus to acquire the potential to cause an epidemic[2], single amino acid substitutions in the HA are sufficient for a virus to escape neutralization by monoclonal antibodies[11]. The three-dimensional structure of the HA of an antigenic variant presented here indicates that the substitution of an aspartic acid for a glycine, without any significant changes in the positions of the atoms in the rest of the HA molecule, is a sufficient alteration to reduce by three orders of magnitude the binding of a monoclonal antibody. The absence of other structural changes in the variant HA, in turn, proves that the monoclonal antibody used to select this variant must bind directly to the region of the HA surface designated site A by Wiley *et al.*[2].

Since submitting this manuscript we have found that H. H.-L. Shih, J. Brady and M. Karplus (unpublished) have independently and with no prior knowledge of our results successfully predicted the structural changes in the mutant V3a, relative to the parent protein. Using a perturbation approach making use of the empirical energy function program CHARMM[23], they calculated a conformational potential energy surface[24] for the aspartic acid side chain in the presence of the rest of the protein Energy refinement[23] of the low energy conformations on this surface yielded side chain torsion angles for Asp 146 with ±20° of the X-ray results. Further, the prediction of an adjustment

Table 1 Haemagglutination-inhibition reactions of X31 virus and antigenic mutant V3a

	Monoclonal antibody				
Virus	HC3a	HC31	HC101	HC83	HC263
X31	12,800	6,400	12,800	6,400	25,600
V3a	>100	6,400	12,800	6,400	25,600

Haemagglutinin-inhibition reactions were done by standard procedures. The values shown are the reciprocals of the highest dilutions of the antibodies at which haemagglutination was inhibited The specificities of the different monoclonal antibodies are defined by the amino acid substitutions observed in antigenic variants of X31 virus that the individual antibodies select. Thus, antibody HC3a selects mutants with amino acid substitutions at residue 146; HC31 at residue 198; HC101 at residue 63; HC83 at residue 193; and HC263 at residue 158. All monoclonal antibodies tested, other than HC3a which was used to select V3a, react with X31 and V3a equally.

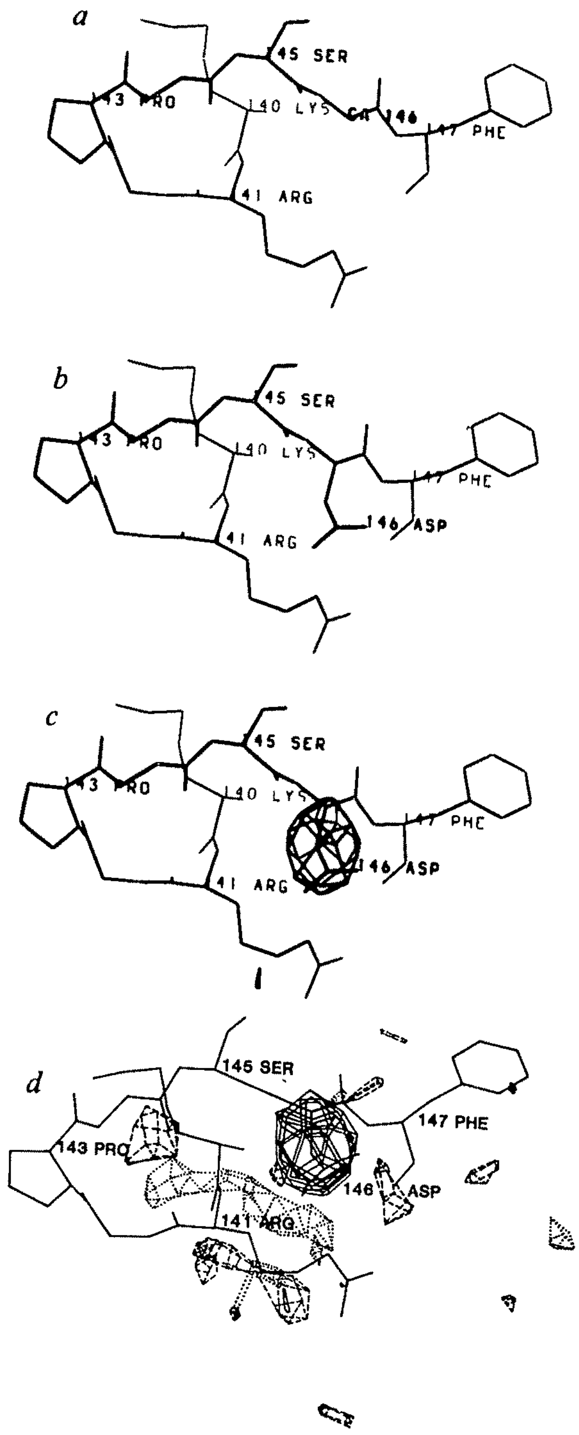

Fig. 2 *a*, Structure of the amino acid 140-147 loop which contains a glycine at position 146 in the parent HA. Atomic coordinates for the parent structure[15] were obtained by model building (I. A. Wilson and D.C.W.) on a version of the BILDER program[20] modified by Robert Ladner. These were refined to an *R* factor of 0.26 after six cycles of restrained least-squares refinement[21] where the contribution of the structure factor to the least-squares equation was evaluated by the gradient-curvature method on a difference map (ref. 22 and M. Lewis and D. Rees, personal communication). ($R = \Sigma|s_iI_{hi} - \bar{I}_h|/\Sigma\bar{I}_h$) where s_i = scale factor (including film temperature factor) for crystal *i*, and I_{hi} = intensity of reflection *h* of crystal *i*.) Exact 3-fold symmetry was imposed on the HA trimer in the crystallographic asymmetric unit by refining only a monomer's coordinates from 3-fold averaged difference maps. An overall *B* factor of 14 was used. Details of the refinement will be published elsewhere. *b*, The coordinates of the 140-147 loop of the antigenic variant V3a showing the location of the Asp (for Gly) substitution. Note that no conformational changes are observed between *a* and *b*. The V3a loop coordinates were obtained from model building on a $2F_0 - F_c$ map after refining the X31 coordinates (minus the loop) against the V3a data. *c*, The V3a difference map (F_{obs} V3a $- F_{obs\,X31}$) showing the 12σ peak at Asp 146. The only significant difference is at the position expected by the addition of the Asp 146 side chain instead of Gly 146 in the wild type. The difference Fourier was calculated using observed parent and variant structure factors with the refined phases described for *a*. *d*, The same as *c* with additional positive (dashed) and negative (dotted) contours at the noise level, 3σ. The interpretable 3σ peaks are a ridge of difference density indicating a small shift in the position of the side chain of Arg 141, which is within hydrogen bonding distance of Asp 146. (This figure was produced with an Evans and Sutherland PS-300 on the version of FRODO written by J. W. Pflugrath, M. A. Saper, B. Bush and A. Jones.)

in the position of Arg 141 to improve the hydrogen bond to the carboxyl group of Asp 146 led to our finding its displacement in the experimental difference map. Details of the method and results will be given separately.

We thank David Stevens and Rose Gonsalves for assistance, Eugene Brown of Genetic Institute for synthesizing one of the oligonucleotide primers, and acknowledge support from NIH AI 13654 (D.C.W.). M.K. was the recipient of fellowship DRG-542 from the Damon Runyon-Walter Winchell Cancer Fund. We also thank Henry H.-L. Shih, John Brady and Martin Karplus for allowing us to quote from their unpublished results predicting the structure of the single-site mutant

Errata

A general circulation model of water isotope cycles in the atmosphere

S. Joussaume, J. Jouzel & R. Sadourny

Nature **311**, 24-29 (1984)

In this article, the order of the authors was incorrect. It appears correctly above.

Sequential late Cenozoic structural disruption of the northern Himalayan foredeep

D. W. Burbank & R. G. H. Raynolds

Nature **311**, 114-118 (1984)

The above article was published with the name of the third author spelt incorrectly as Reynolds.

Much ado about CO_2

John S. Perry

Man-Made Carbon Dioxide and Climatic Change: A Review of the Scientific Problems.
By P.S. Liss and A.J. Crane.
Geo Books, Regency House, 34 Duke Street, Norwich NR3 3AP, UK: 1983. Pp.127. Hbk £8.50, $17; pbk £3.95, $7.80.
Carbon Dioxide — Emissions and Effects (Report No. ICTIS/TR18).
By Irene M. Smith.
IEA Coal Research, 14-15 Lower Grosvenor Place, London SW1W 0EX: 1982. Pp.132. £10 (IEA countries), £20 (elsewhere).
Climate and Energy Systems: A Review of their Interactions.
By Jill Jäger.
Wiley: 1983. Pp.231. £19.95, $39.95.
Our Threatened Climate: Ways of Averting the CO_2 Problem through Rational Energy Use.
By Wilfrid Bach.
Reidel: 1983. Pp.368. $29, Dfl. 95, £24.25.

THE Niagara of writings on carbon dioxide, of which a sampling of the output over the past year or so forms the basis for this review, suggests that the gas is becoming an essential nutrient not only for green plants but for a large segment of the scientific community as well. Indeed, Roger Revelle — who, with Hans Suess, once termed man-made emissions of CO_2 a "geophysical experiment" — now wryly muses about the CO_2 "cottage industry". What is all the fuss about?

The following is an attempt to compress a large bookcase into a paragraph. The Earth's carbon is distributed among crustal sediments, the ocean, a thin layer of living materials, a wisp of CO_2 in the air and millions of years' accumulation of fossilized organic material in the forms of coal, oil and gas. By burning the fossil matter and by converting carbon-rich forest to thinly vegetated agricultural land, we move carbon atoms into the atmosphere in the form of CO_2. Some of these atoms find new homes in the ocean or the living biota, but about half seem to stay in the air. Globally, we are injecting more than 5×10^9 tonnes of carbon into the environment each year, and the atmosphere's carbon dioxide concentration — now about 340 parts per million by volume — is increasing by about 1 ppm per year. This would be no great matter, except for the fact that CO_2 is a good radiator and absorber of thermal (infrared) radiation. Thus, increasing airborne CO_2 increases the effectiveness of the cool upper layers of the atmosphere as radiators and absorbers, and reduces the direct export of radiant energy from the Earth's surface to space. The lower atmosphere and surface must thus run at a higher temperature to make good the planet's energy accounts with the Sun and the cosmos. Altered heating and higher mean temperatures mean changes in climate, changes that must concern a world whose food supply depends on what Paul Waggoner has termed "the annual lottery of the weather". Is fossil fuel like tobacco, then: convenient and pleasant to burn, but with nasty long-term consequences?

To assess the issue, one must systematically explore every link in a long chain of processes. The marvellously complex nature of that chain has inspired increasing numbers of authors to try to sum up various findings and attempt a synthesis of the structure as a whole. The four volumes addressed here fall into this category. As in the classic *Rashomon* tale, each witness sees the scene through a filter of his own experience and background and tells a somewhat differently tinted story.

Liss and Crane, both associated with the electric power industry, follow a straightforward path through the major scientific questions attending CO_2 to their implications for future energy production from fossil sources. The authors' expositions of crucial physical processes such as ocean chemistry and radiation are clear, concise and accurate. Indeed, their analysis of the mechanics of the greenhouse effect is by a long mile the best short account in print. Irene Smith, writing for the coal and energy community, presents an objective and meticulously documented review that favours scientific results over methods and response strategies over unanswered questions. Jill Jäger takes a virtually orthogonal tack; after a notably complete essay on climate and carbon dioxide, she systematically assesses the connections between all aspects of energy production and climate. Her discussions of particulates, of solar and renewable energy sources, and of the effects of climate on the energy sector are particularly valuable. Finally, like his colleagues, Wilfrid Bach reviews the elements of the problem, but he never strays far from a path to its solution. Thus he focuses on the human society that is the source of CO_2 emissions, that must bear the consequences and that alone can devise means to cope with them. (In passing, it should be said that Jill Jäger contributes to this collection not only as author of her own book and translator of Bach, but also as the prolific J. Williams who appears in the notably comprehensive bibliographies of all of the books.)

Despite their diverse approaches, the authors converge in their assessments. Indeed, their findings differ little from those of another recent volume about which I can hardly claim an unbiased view — *Changing Climate*, a report of the US National Academy of Sciences published in 1983.

- *How will the atmospheric CO_2 change?* This depends mostly on how much energy future populations will want and where they will get it. Forecasting approaches are diverse and predictions for the distant future span a wide range. Liss and Crane simply extrapolate constant growth rates, while Smith, Jäger and Bach review a number of forecasts, tending to favour the projections of the International Institute for Applied Systems Analysis. Jäger's discussion is particularly thorough, taking into account, for example, the logistical and sociopolitical obstacles to burning huge amounts of coal. Allowing for the uncertainties in the disposition of excess carbon by the ocean and atmosphere, all projections show rapid growth in airborne CO_2 as we move into the twenty-first century. Using an economic model in a Monte Carlo simulation, Nordhaus (in the NAS report) projected a probable doubling of airborne CO_2 in the third quarter of the century, with a broad band of uncertainty that comfortably envelopes the other studies.
- *What effects will there be on climate?* Numerical models of the climate system indicate that a doubled concentration of atmospheric CO_2, if maintained indefinitely, would produce a mean global warming of around 3°C. Regional changes in weather and precipitation would be more marked, but models cannot yet identify them reliably. It does seem that the poles would warm more than the tropics, and that mid-latitude summers would be longer, warmer and thus drier. Analogies with past and contemporary climate — carefully reviewed by Jäger — provide useful insights but no definite conclusions. Changes will be slowed and complicated by the heat buffering of the oceans, and other radiation-absorbing trace gases injected anthropogenically may add to the influence of CO_2. A particularly good discussion of the latter area is presented by Bach.
- *What are the implications of these changes?* In a warmer world, sea water will expand, glaciers will melt and sea level will rise (70 cm in a century according to the NAS study). Changes in weather will influence almost every aspect of human life — energy demand, agriculture, water resources, fisheries, settlement patterns, health and recreation, to follow Bach's exhaustive taxonomy. Especially troublesome are possible changes in

precipitation, evaporation and runoff that might affect the availability of water for irrigation. All of the authors see these changes as potentially serious, but only Bach agrees with a recent assessment by the US Environmental Protection Agency (*Can We Delay a Greenhouse Warming?*, which was also published last year) that the implications are unequivocally catastrophic.

- *What should we do?* If we side with all of the authors except Bach, giving weight to the huge uncertainties and the adaptive capabilities of life on Earth, then the wise course is to be alert for signs of nasty consequences (none is yet evident), to take sensible steps to reduce damage to the environment, and to develop a range of alternative options for energy supply and for living in a changing climate. If we share Bach's assessment then a much more active policy is called for. He proposes aggressive energy conservation measures, reforestation, soil conservation and the expeditious development of renewable energy resources. In the short term, the cautious and activist prescriptions may differ little in their practical effect, and by the end of the century, the NAS report proposes, we will know a lot more if we keep up the pace of research. In the meantime, the implementation of elements of Bach's prescription can only be to the good — fear of climate change, like fear of cancer, may lead us into healthier habits that could spare us from many other hazards.

Reading these books leads one to conclude that the CO_2 "cottage industry" is serving the public well by clearly illuminating the complexities of this web of scientific and social issues. Others in the business have different strengths. In a popular vein, John Gribbin's *Future Weather and the Greenhouse Effect* (Delacorte, 1982) has much to recommend it, if its more mystical elements are disregarded. Wilfrid Bach and colleagues have given us two earlier and excellent reviews — *Man's Impact on Climate* (Elsevier, 1979) and *Carbon Dioxide: Current Views and Developments in Energy/Climate Research* (Reidel, 1983). Societal aspects were explored by W.W. Kellogg and R. Schware in *Climate Change and Society* (Westview, 1981), while a detailed scientific analysis was orchestrated by Gordon J. MacDonald (*The Long-Term Impacts of Increasing Atmospheric Carbon Dioxide Levels*; Ballinger, 1982). A most comprehensive review, edited by William C. Clark, is *Carbon Dioxide Review: 1982* (Clarendon, 1982). And the NAS report, *Changing Climate*, a compendium of reviews, original contributions and synthesis, has already been mentioned.

The books of current vintage contribute much to this literature, and all can be recommended. Both Jäger and Bach are distinctive and important additions. Jäger's comprehensive view of climate through the prism of energy is unique and illuminating. Bach, though regrettably impeded by abominable computer typesetting, presents an impressively scholarly and exhaustive treatment. While his road leads to but one conclusion, it is broad and solidly built.

The next few years will bring further contributions. The US Department of Energy will soon release an assessment of the knowledge and conclusions emanating from its massive research programme, and an international effort is laying the groundwork for a 1985 intergovernmental conference. Thus, as was observed in the NAS report, while CO_2 may be a worrisome issue, it may also be a healthy stimulus which forces us to address seriously the long-term maintenance of our planetary home. □

Cells: bags of water or blobs of jelly?

D.A.T. Dick

In Search of the Physical Basis of Life.
By Gilbert N. Ling.
Plenum: 1984. Pp. 791. $79.50, £67.57.

QUANTITATIVE membrane theories, such as those of Boyle and Conway and the Hodgkin–Katz–Goldman equation, achieved spectacular success in the 1940s. These, along with Hodgkin and Keynes's demonstration of rapid potassium diffusion in the squid axon, induced a widespread view among physiologists that the cell is simply a membrane-bounded bag. In it, so the story ran, is a fairly homogeneous, aqueous soup of proteins and inorganic ions, the composition and electrical potential of which is controlled by the membrane. By contrast, a heterodox group of physiologists — led in particular by Troschin in Russia and by Ling in the United States — has maintained that the cell is essentially a blob of jelly, held together by controlled intermolecular forces between protein molecules to which water and the ionic constituents are variably bound. This view, called by Ling the association–induction theory, has been pursued to the extent of denying any significant role to the cell membrane.

Neither of these extreme stances is of course correct. In addition to the ample evidence for the function of the cell membrane, it is now known that the cellular matrix possesses a structure of microtubules and microfilaments (see for example *J. Cell Biol.* **99**, No. 1, Pt 2; 1984), that in some cells the distribution of ions (particularly sodium and potassium) is not uniform within the cell, and that at least some cellular water is bound. Thus there is sore need of an impartial review of alternative theories of the cell.

Dr Ling's book is divided into five sections, the first of which surveys concepts in cell physiology in a historical framework (here the most important chapter is the fifth which deals with the evidence for and against the membrane theory of the cell). The second section gives a full account of Ling's association–induction theory, particularly in relation to the control of the sodium, potassium and water contents of the cell. The third is largely devoted to the experimental work of Ling and his colleagues in support of the association–induction theory, while the fourth gives an account of mitochondria, muscle and epithelial transport, usually rejecting conventional physiological views and reinterpreting the data in terms of the association–induction hypothesis. The final section describes recent work on protein synthesis, growth and differentiation, and cancer, and offers speculative interpretations of these phenomena again based upon the association-induction hypothesis.

Dr Ling describes his book as "at once a monograph, a science history tract, and a textbook". A monograph, it certainly is, but it has little of the objective judgement and impartiality normally associated with a history or a textbook. For example there are 106 references to the work of Dr Ling while some quite distinguished cell physiologists are represented by a couple of citations only. A distinctive historical feature is a series of portraits, most of them of justly prominent figures but with some bizarre omissions (and inclusions); often one cannot help feeling that the space occupied by the photograph would have been better employed by a more adequate treatment of the work of the scientist portrayed. For example Ling's survey of the sodium-potassium ATPase of the cell membrane, embracing the work of J.C. Skou, E.T. Dunham, I.M. Glynn, R.L. Post and S.L. Bonting, occupies but a page and a half.

Dr Ling appears to be constitutionally an advocate, rather than a judge, and he has set out to win his case by presenting every conceivable argument in support of his own position and giving the other side inadequate and unbalanced treatment. This is a pity. Since the 1950s majority views of the cell have moved significantly nearer to those of Dr Ling, but in this book he harms his own case by overstatement. What we need now is a judge, not an advocate. □

D.A.T. Dick is Cox Professor of Anatomy in the University of Dundee.

From the laboratory to the clinic

W. F. Bynum

Science and Medicine in France: The Emergence of Experimental Physiology, 1790–1855.
By John E. Lesch.
Harvard University Press: 1984. Pp.276. $25, £22.

A SCIENTIST's proclaimed self-image may conceal as much as it reveals. Isaac Newton likened himself to a boy playing on the seashore, "diverting myself in now and then finding a smoother pebble or a prettier shell than ordinary, whilst the great ocean of truth lay all undiscovered before me". This is a charming image, but one which hardly does justice to Newton's complex psychology, or to his belief that he had seen into the heart of things. François Magendie compared himself to "a rag-pricker: with my spiked stick in my hand and my basket on my back, I traverse the field of science and I gather what I find". Equally charming this, but equally inadequate as an account of Magendie's philosophy of discovery. Certainly he did not possess the philosophical sophistication of his pupil Claude Bernard (1813–1878), by whom this statement of Magendie was recorded and who rather liked to cast his teacher into the role of John the Baptist as foil to himself as Messiah. But Magendie (like Bernard) was concerned with the dialectic between basic science and clinical medicine, and it is this which is a central theme in John Lesch's book.

Magendie (1783–1855) was a child of the French Revolution, a product and a participant in the "hospital medicine" which, particularly after the reorganization of the Paris Medical School in 1794, came to dominate French medical education. This form of clinical medicine was firmly rooted in the hospital, where medical students were to be based from the first day of their education and where they were to "read little, see much, do much". The high priests of hospital medicine — Corvisart, Laennec, Louis — stressed the importance of the local lesion as opposed to the generalized symptom, the lesion to be discovered by careful physical diagnosis (made more systematic after Corvisart popularized percussion and Laennec invented the stethoscope) and confirmed by autopsy. Every hospital physician was to be his own pathologist, permitting diseases such as phthisis, pneumonia and typhoid to be conceptualized in terms of more constant lesion than more variable symptom. For many doctors of the French school, the sciences of physics, chemistry, physiology and even microscopy were "accessory" rather than "basic" to the medical enterprise: accessory and potentially dangerous, for they encouraged speculation and system-building in advance of the "facts" demonstrable by pathological anatomy.

This aspect of "hospital medicine" has been elucidated in books such as E.H. Ackerknecht's *Medicine at the Paris Hospital, 1794–1848* (The Johns Hopkins University Press, 1967) and Michel Foucault's *Birth of the Clinic* (published in English translation by Tavistock in 1973). But while Lesch recognizes the cogency of their work, the value of his own lies in its patient examination of an equally rich tradition in early-nineteenth-century French medicine: a tradition which recognized the value of experimental science. He scrutinizes three sciences, chemistry, pharmacology and physiology, in each of which Magendie was a key figure.

A critical chemical tradition in French science dates back to the formation (in 1776) of the Société Royale de Médecine and to the rigorous attempt by prominent members of that Society, especially Antoine Fourcroy (1755–1809), to apply the newer analytical methods of chemistry to isolate and identify the active ingredients of common medical preparations. From the turn of the century the discovery of plant alkaloids—including emetine, strychnine, codeine, quinine and morphine—had demonstrated the value of the "analytical method", and had provided Magendie with the justification for producing his own *Formulaire* (1821), a therapeutic manual based on the notion of pure substances rather than polypharmic preparations. In using the word "pharmacology" in 1805, J.B.G. Barbier (1776–1865) had insisted that the pharmacologist had to be both chemist (to identify the active substance) and physiologist (to elucidate its precise actions). It was particularly in the latter guise that Magendie pursued his experimental investigation of strychnine, prussic acid and ipecacuanha. His relations with the Paris hospitals were chequered, but various clinicians helped him in his researches; and, in 1830, he became director of a women's ward in the Hôtel Dieu, where he was able to conduct more systematic clinical trials.

Magendie's clinical work (some of it simply attempting to cope with the seriously ill, as in the 1832 cholera epidemic when this most gifted experimentalist of his generation treated 594 cholera victims between March and August) reminds us of the complexity of the relationship between science and medicine during the period. The interplay between the two can be seen in Magendie's concept of "pathological physiology", for much of his most famous research—on the cerebro-spinal fluid, on the functions of the posterior and anterior roots of the spinal nerves, on localization within the central nervous system—was laboratory based but clinically informed. Lesch establishes continuity between the methods and problems of the late Magendie and the early Bernard, just as he also sees important legacies for Magendie from the experimental work of Xavier Bichat (1771–1802).

Much of Lesch's monograph consists of rather detailed expositions of the experimental chemical, pharmacological and physiological results obtained by French medical scientists of Magendie's era. Some of this may be of specialist historical interest. But the general problem he addresses—what place has experimental science in medicine?—is one of great topicality. Our own answers may not be the same as those proposed in nineteenth-century France, but Lesch's book does illuminate an important historical moment in that continuing dialogue.

W.F. Bynum is at the Wellcome Institute for the History of Medicine, London.

Meeting of minds in a magnetic field

Robert S. Coe

Geomagnetism of Baked Clays and Recent Sediments.
Edited by K.M. Creer, P. Tucholka and C.E. Barton.
Elsevier Scientific: 1983. Pp. 324.
Dfl. 125, $53.25.

K.M. Creer and his co-editors frankly confess to holding "mixed views about the publication of symposium proceedings". Such pessimism was misplaced; to my mind, they have succeeded admirably in avoiding the pitfalls that doom most books of this genre to a limited readership and transient life.

Several factors have contributed to the success of this volume. First, the subject of geomagnetism has entered one of those periods in which the various sub-disciplines are bubbling with excitement and appear to be converging on common (but as yet dimly perceived) ground. Satellites such as MAGSAT have revolutionized the business of global measurement and description of the present geomagnetic field, cryogenic magnetometers have greatly increased the rate that data about the ancient geomagnetic field can be obtained from weakly magnetized rocks, and computers have immeasurably improved our ability to store and manipulate data and perform the calculations required for increasingly sophisticated models of geodynamos. Geomagnetists are now talking to palaeomagnetists; theory is meeting observation and experiment.

Secondly, the Fourth Assembly of the International Association of Geomagnetism and Aeronomy held in 1981 in Edinburgh—including the Symposium on Time Scales of Secular Variation, from which the core of papers published in this volume is drawn—was graced with an unusual number of truly fine contributions, and came at a time when the subject is manageable in scope and sorely in need of review. The main reason, however, that this book is definitely more than just another symposium volume lies in the clear effort taken by the editors to achieve a logical organization, adequate coverage and balance, and a semblance of uniformity of style.

The central theme is the behaviour of the geomagnetic field over the past several tens of thousands of years, as deduced from the remanent magnetization of baked clays and lake sediments. The 33 contributions (by 40 authors) are grouped into four chapters, the first of which contains brief and often interesting critiques of the most relevant magnetization processes, including thermoremanent magnetization, detrital remanent magnetization and shear remanent magnetization. The second consists of similar treatments of selected dating techniques (palynology, radiocarbon, tree-rings and varves, lead-210 and thermoluminescence).

The third chapter is the longest and most highly developed. It is distinguished by a particularly clear and informative review of techniques for archaeointensity determination by M.J. Aitken; by summaries of archaeomagnetic results up to 1981 for Greece, Bulgaria and Yugoslavia, Egypt, the Near East, the USSR, China, Japan, the United States, Peru and Australia; and by a perceptive analysis of global intensities for the past 50,000 years by M.W. McElhinny. The final chapter consists of presentations of palaeomagnetic data—many of which show encouraging consistency—of lake sediments from Europe, North America, Argentina and Australia, and cave sediments from Europe, as well as reviews of mathematical techniques for analysis of directional data as a function of depth or time. Throughout the book, the various topics are woven together by means of introductory sections and occasional summary discussions within each chapter. An "Epilogue" by the editors, containing their own analysis, interpretation and conclusions, also helps to unify the book and is a stimulating contribution in its own right.

One can always find things to complain about. I found myself wishing at times that the coverage were more encyclopaedic, and resolving to get my eyes examined because of the small camera-ready type-face with commas that are almost indistinguishable from full points. While it is impossible for a symposium volume to have the same intellectual impact as a book written by one or a few excellent scientists who are also excellent writers, this is about as close as you can get; newcomers can read it as a detailed and relatively unbiased introduction to the field, and practising specialists will find it a handy reference for quite some years. Simply put, it is one of the most effective multi-author works that I have encountered in the earth sciences. ☐

Robert S. Coe is a Professor in the Department of Earth Sciences at the University of California, Santa Cruz.

Instruments of change

Alan Braithwaite

Microcomputers and Laboratory Instrumentation.
By David J. Malcolme-Lawes.
Plenum: 1984. Pp. 246.
$35, £29.75.

MOST scientists and technologists are now faced with the challenge of the microprocessor chip. It is present in all types of instrumentation, to control the mechanics and optimize parameters, and also to collect and process data. It is still possible to lead the quiet life of an alchemist, but the march of progress means that sooner or later almost everyone in a laboratory will have to wrestle with a new language — the language of the computer — and with sophisticated instruments employing arrays of chips.

Programming languages are not too difficult to learn. They use an understandable syntax, and there are numerous books on the topic. The hardware presents more of a problem but, surprisingly, there are few accounts of the subject as it applies to scientific instrumentation and intended for the practising scientist. David Malcolme-Lawes has written such a text. It sets out to present in clear, understandable terms the overall concept of microcomputer systems, microprocessors and various logic chips incorporated into digital and interfacing circuitry. Further, many computers are used for collection of data from detectors and transducers, and also to control instrument functions, switches, relays, heaters and so on, and these principles too are explained both in general terms and in more detail, including the logic required to buffer and interface digital signal buses and interconnect equipment. For the more enterprising readers there is also a chapter on system design concepts and the construction of interfaces and microcomputer equipment.

It is quite possible to read the book selectively to obtain an overview, but the main purpose is to cover all the necessary background concepts relating to the nature and handling of instrument and transducer signals, microcomputer systems and interfacing concepts. Overall, the writing reflects the teaching experience of the author, as does the inclusion of a large number of diagrams to supplement the text — in this subject in particular, a picture is indeed worth a thousand words.

The net result is a well-presented, readable book which provides a sound introduction to microcomputers in the laboratory and also to the principles and concepts of microprocessor systems and interfacing. Scientists and technologists seeking to get to grips with new technological developments, and students for whom laboratory instrumentation is part of their course, will find it very helpful. My only plea is that the publishers should consider issuing a paperback edition; I think they would find it worth their while. ☐

Alan Braithwaite is a Senior Lecturer in Analytical Chemistry in the Department of Physical Sciences, Trent Polytechnic, Nottingham.

Astrodynamics 1983. Advances in the Astronautical Sciences, Vol. 54 Parts I & II. T.G. TSENG *et al.* (eds). *American Astronautical Society: 1984. Pp.653 & 1,330. Hbk ISBN 0-87703-190-7, 0-87703-190-8; pbk ISBN 0-87703-191-6, 0-87703-191-6. Np.*

Connected Components in Binary Images: The Detection Problem. By CHRISTIAN RONSE and PIERRE A. DEVIJVER. *Wiley: 1984. Pp.165. ISBN 0-86380-016-5. £24.*

Interstellar Chemistry. By W.W. DULEY and D.A. WILLIAMS. *Academic: 1984. Pp.264. ISBN 0-12-223360-3. £29, $45.*

The Solar System. By ROMAN SMOLUCHOWSKI. *Scientific American Books: 1984. Pp.173. ISBN 0-7167-1492-2. $27.95.*

Technology

Advances in Cryogenic Engineering Materials, Vol.30. A.F. CLARK and R.P. REED (eds). *Plenum: 1984. Pp.998. ISBN 0-306-41704-9. Np.*

Atmospheric Turbulence: Models and Methods for Engineering Applications. By HANS A. PANOFSKY and JOHN A. DUTTON. *Wiley: 1984. Pp.397. ISBN 0-471-05714-2. £47.45, $66.45.*

Flexible Assembly Systems. Assembly by Robots and Computerised Integrated Systems. By A.E. OWEN. *Plenum: 1984. Pp.231. ISBN 0-306-41527-5. Np.*

Science, Technology and Society Today. MICHAEL GIBBONS and PHILIP GUMMETT (eds). *Manchester University Press: 1984. Pp.198. Hbk ISBN 0-7190-0905-7; pbk ISBN 0-7190-0878-6. Hbk £11.50; pbk £4.50.*

Chemistry

Advanced Organic Chemistry 2nd Edn. Part A: Structure and Mechanisms. By FRANCIS A. CAREY and RICHARD J. SUNDBERG. *Plenum: 1984. Pp.726. Hbk ISBN 0-306-41087-7; pbk ISBN 0-306-41198-9.*

Analysis Using Glass Electrodes. By PETER W. LINDER, RALPH G. TORRINGTON and DAVID R. WILLIAMS. *Open University Press: 1984. Pp.148. ISBN 0-335-10420-7. £20.*

75th Jubilee Conference on Helium — 4. J.G.M. ARMITAGE (ed.). *Wiley: 1983. Pp.211. ISBN 9971-966-23-9. £20.75.*

Molecular Diffusion and Spectra. By WILLIAM T. COFFEY, MYRON W. EVANS and PAOLO GRIGOLINI. *Wiley: 1984. Pp.378. ISBN 0-471-87539-2. £47.50.*

Organometallic Chemistry, Vol.12. F.G.A. STONE and E.W. ABEL (eds). *Royal Society of Chemistry: 1984. Pp.498. ISBN 0-85186-601-8. £82.*

Reactions of Small Transient Species: Kinetics and Energetics. A. FONTIJN and M.A.A. CLYNE (eds). *Academic: 1983. Pp.488. ISBN 0-12-262040-2. £49.80, $89.*

Room Temperature Phosphorimetry for Chemical Analysis.•By TUAN VO-DINH. *Wiley: 1984. Pp.304. ISBN 0-471-87884-7. £47.50.*

Solid-Liquid Separation. JOHN GREGORY (ed.). *Wiley: 1984. Pp.363. ISBN 0-470-20021-9. £32.50.*

Surfactants in Solution, Vols 1 & 2. K.L. MITTAL and B. LINDMAN (eds). *Plenum: 1984. Pp.705, 1,432. ISBN 0-306-41483-X; 0-306-41484-8. Np.*

Theilheimer's Synthetic Methods of Organic Chemistry. A.F. FINCH (ed.). *Karger: 1984. Pp.620. ISBN 3-8055-3817-0. $346.25.*

Topics in Carbon-13 NMR Spectroscopy. GEORGE C. LEVY (ed.). *Wiley: 1984. Pp.282. ISBN 0-471-09857-4. £54.65, $57.50.*

Physics

Advances in Liquid Crystals, Vol. 6. GLENN H. BROWN (ed.). *Academic: 1983. Pp.268. ISBN 0-12-025006-3. $80.*

Classical Mechanics: A Course of Lectures. By A.K. RAYCHAUDHURI. *Oxford University Press: 1984. Pp.210. ISBN 0-19-561343-0. £7.50.*

The Creation of Quantum Mechanics and the Bohr-Pauli Dialogue. Studies in the History of Modern Science 14. *Reidel: 1984. ISBN 90-2771648-X. $34.50.*

The Dynamic World of Physics. By ROBERT T. DIXON. *Charles E. Merrill: 1984. Pp.560. ISBN 0-675-20093-8. Np.*

Foundations of Quantum Mechanics in the Light of New Technology. S. KAMEFUCHI *et al.* (eds). *Physical Society of Japan: 1984. Pp.377. ISBN 4-89027-001-9. Np.*

Fusion: An Introduction to the Physics and Technology of Magnetic Confinement Fusion. By WESTON M. STACEY. *Wiley: 1984. Pp.260. ISBN 0-471-88079-5. £39.50.*

Isotope Shifts in Atomic Spectra: Physics of Atoms and Molecules. By W.H. KING. *Plenum: 1984. Pp.208. ISBN 0-306-41562-3. $37.50.*

Methods in Radiative Transfer. WOLFGANG KALKOFEN (ed.). *Cambridge University Press: 1984. Pp.450. ISBN 0-521-25520-8. £25, $49.50.*

Perspectives in Nuclear Physics at Intermediate Energies. S. BOFFI, C. CIOFI DEGLI ATTI and M.M. GIANNINI (eds). *Wiley: 1984. Pp.546. ISBN 9971-966-32-8. £49.*

Physical Sciences and History of Physics. Boston Studies in the Philosophy of Science, Vol.82. R.S. COHEN and M.W. WARTOFSKY (eds). *Reidel: 1984. Pp.259. ISBN 90-277-1615-3. $39.50.*

Secondary Ion Mass Spectrometry SIMS IV. Springer Series in Chemical Physics 36. A. BENNINGHOVEN *et al.* (eds). *Springer-Verlag: 1984. Pp.502. ISBN 3-540-13316-X/0-387-13316-X. $38.50.*

Statistical Physics & Chaos in Fusion Plasmas. C.W. HORTON and L.E. REICHL (eds). *Wiley: 1984. Pp.361. ISBN 0-471-88310-7. £80.75.*

Symplectic Techniques in Physics. By VICTOR GUILLEMIN and SHLOMO STERNBERG. *Cambridge University Press: 1984. Pp.468. ISBN 0-521-24866-3. £32.50, $49.50.*

Earth Sciences

Catchment Experiments in Fluvial Geomorphology. T.P. BURT and D.E. WALLING (eds). *Geo Books: 1984. Pp.608. Pbk ISBN 0-86094-137-X. Pbk £28.50.*

Chemistry of Particles, Fogs and Rains Acid Precipitation Series Vol. 2. JACK L. DURHAM (ed.). *Butterworth: 1984. Pp.262. ISBN 0-250-40567-9. Np.*

Constitution of the Earth's Interior. J. LELIWA-KOPYSTYNSKI and R. TEISSEYRE (eds). *Elsevier: 1984. Pp.368. ISBN 0-444-99646-X. $83, Dfl. 195.*

Deposition Both Wet and Dry. Acid Precipitation Series Vol. 4. BRUCE B. HICKS (ed.) *Butterworth: 1984. Pp.197. ISBN 0-250-40569-5. Np.*

Direct and Indirect Effects of Acidic Deposition on Vegetation. Acid Precipitation Series Vol. 5. RICK A. LINTHURST (ed.). *Butterworth: 1984. Pp. 117. ISBN 0-250-40570-9. Np.*

Early Biotic Responses to Advancing Lake Acidification. Acid Precipitation Series Vol. 6. GEORGE R. HENDREY (ed.) *Butterworth: 1984. Pp.173. ISBN 0-250-40571-7. Np.*

Erosion and Sediment Yield: Some Methods of Measurement and Modelling. R.F. HADLEY and D.E. WALLING (eds.) *Geo Books: 1984. Pp.218. Hbk ISBN 0-86094-158-2; pbk ISBN 0-86094-141-8. Hbk £13.50; pbk £9.*

Geography & Population: Approaches and Applications. JOHN I. CLARK (ed.) *Pergamon 1984. Pp.245. Hbk ISBN 0-08-028781-6, pbk ISBN 0-08-028780-8. Pbk £6.95, $11.50.*

Geological Aspects of Acid Deposition. Acid Precipitation Series Vol. 7. OWEN P. BRICKER (ed.) *Butterworth: 1984. Pp.143. ISBN 0-40572 5. Np*

Groundwater as a Geomorphic Agent. R. G. LAFLEUR (ed.). *Allen & Unwin: 1984 Pp 390 ISBN 0-04-5517069-5. £30, $50*

Handbook on the Physics and Chemistry of Rare Earths, Vol. 6. K.A.G. SCHNEIDNER and L. EYRING (eds). *North-Holland 1983. Pp 604 ISBN 0-444-86592-6. $119.25.*

Ice Sheets and Climate. By J. OERLEMANS and C.J. VAN DER VEEN. *Reidel 1984 Pp 217 ISBN 90-277-1709-5. $34.50.*

London Illustrated Geological Walks. By ERIC ROBINSON. *Scottish Academic Press 1984 Pp 97 ISBN 0-7073-0350-8. Pbk £4 95*

Materials Science of the Earth's Interior. ICHIRO SYNAGAWA (ed.). *Reidel 1984 Pp 653 ISBN 90-277-1649-8. $120.*

Meterological Aspects of Acid Rain. Acid Precipitation Series Vol. 1. CHANDRAKANT M. BHUMRALKAR (ed.). *Butterworth 1984 Pp 243 ISBN 0-250-40566-0. Np*

Mineral Resources Appraisal: Mineral Endowment, Resources, and Potential Supply. Concepts, Methods and Cases. By DEVERLE P. HARRIS. *Oxford University Press: 1984. Pp 445 ISBN 0-19 854456-[illegible] £37.50.*

Modelling of Total Acid Precipitation Impacts. Acid Precipitation Series Vol. 9. JERALD L. SCHNOOR (ed.). *Butterworth: 1984 Pp 222 ISBN 0 250 40573 1 Np.*

Satellite Sensing of a Cloudy Atmosphere. Observing the Third Planet. ANN HENDERSON-SELLERS (ed.). *Taylor & Francis: 1984 Pp 340 ISBN 0-85066-254-0. £18.*

Scandinavia: A New Geography. By BRIAN JOHN *Longman: 1984. Pp.365. Pbk ISBN 0-582-48950-4 Pbk £11.95.*

SO_2, NO and NO_2 Oxidation Mechanisms. Atmospheric Considerations. Acid Precipitation Series Vol. 3. JACK G. CALVERT (ed.) *Butterworth 1984 Pp.254. ISBN 0-250-40568-7 Np*

Environmental Sciences

Air Monitoring Methods for Industrial Contaminants. DAVID A. HALLIDAY (ed.) *Biomedical Publications, Box 495, Davis, California 95617: 1983. Pp.428. ISBN 0-931890-12-8 Np*

Chlorinated Dioxins and Dibenzofurans in the Total Environment. By GANGADHAR CHOUDHARY, LAWRENCE H. KEITH and CHRISTOFFER RAPPE. *Butterworth: 1984 Pp 416 ISBN 0-250-40604-7. £42.*

Handbook of Air Pollution Technology. SEYMOUR CALVERT and HAROLD M. ENGLUND (eds). *Wiley: 1984. Pp 1066 ISBN 0-471-08263-5 £71.20, $74,95.*

Hazardous Waste Land Treatment. KIRK W. BROWN, GORDON B. EVANS and BETH D. FRENTRUP (eds). *Butterworth: 1983 Pp 692 ISBN 0-250-40636-5. £48.*

Identification and Analysis of Organic Pollutants in Air. LAWRENCE H. KEITH (ed.) *Butterworth 1984. Pp.486. ISBN 0-250-40575-X £55*

Liquid Chromatography in Environmental Analysis. JAMES F. LAWRENCE (ed.). *Wiley 1984 Pp 374 ISBN 0-89603-045-8. £48.75*

Toxic Contaminants in the Great Lakes. JEROME O. NRIAGU and MILAGROS S. SIMMONS *Wiley 1984. Pp.527. ISBN 0-471-89087-1 £90.25.*

Biological Sciences

Advances in Cyclic Nucleotide and Protein Phosphorylation Research Vol. 16. SAMUEL J. STRADA and W. JOSEPH THOMPSON (eds) *Raven: 1983. Pp.460. ISBN 0-89004-779-0 $62*

Advances in Cyclic Nucleotide and Protein Phosphorylation Research, Vol. 17A. PAUL GREENGARD *et al.* (eds). *Raven: 1983 Pp 182 Pbk ISBN 0-89004-881-9. Pbk $22.*

Advances in Enzyme Regulation, Vol. 22. By GEORGE WEBER. *Pergamon: 1984. ISBN 0-08-031498-8. £93.75, $150.*

Aging and Recovery of Function in the Central Nervous System. STEPHEN W. SCHEFF (ed.). *Plenum: 1984. Pp.221. ISBN 0-306-41525-9. Np.*

Amphibian Morphogenesis. By HAROLD FOX. *Humana Press: 1984. Pp.320. ISBN 0-89603-043-1. $59.50.*

Applications of Optimal Control Theory in Biomedicine. By GEORGE W. SWAN. *Marcel Dekker: 1984. Pp.285. ISBN 0-8247-7192-3. SwFr. 151.*

Bailey's Textbook of Microscopic Anatomy, 18th Edn. By DOUGLAS E. KELLY, RICHARD L. WOOD and ALLEN C. ENDERS. *Williams & Wilkins: 1984. Pp.909. ISBN 0-683-04568-7. £35.*

The Bee-Eaters. By C.H. FRY. *T. & A.D. Poyser: 1984. Pp.304. ISBN 0-85661-037-2. £19.60.*

Bio-Energy: Technology, Thermodynamics and Costs. By DAVID BOYLES. *Wiley: 1984. Pp.158. ISBN 0-85312-637-2. £16.50.*

Biological Regulation and Development: Volume 3B Hormone Action. ROBERT F. GOLDBERGER and KEITH R. YAMAMOTO (eds). *Plenum: 1984. Pp.312. ISBN 0-306-41442-2. $42.50.*

Biology of Knowledge: The Evolutionary Basis of Reason. By RUPERT RIEDL. *Wiley: 1984. Pp.252. ISBN 0-471-10309-8. £26.*

The Birds of China. By RODOLPHE MEYER DE SCHAUENSEE. *Oxford University Press: 1984. Pp.602. ISBN 0-19-858602-7. £35.*

For the biochemistry laboratory

New ideas in this selection include a simple stopped-flow kinetics system for standard laboratory spectrophotometers and spectrofluorimeters.

- Schwarz/Mann Biotech's new Ultra-Pure grade of caesium chloride is 99.999% pure, specifically designed for use in sensitive density gradient determinations. In using the density gradient technique the optical density of the gradient medium should be as close to zero as possible, particularly when studying nucleoproteins. This new pure caesium chloride has an optical density that is inded near zero across the ultraviolet spectrum, and most critically from 260 to 280 nm.
Circle No. 100 on Reader Service Card.

- The Swiss balance manufacturer Precisa has introduced three new analytical balances featuring enlarged weighing ranges. These instruments offer a weighing capacity of 120 g, 160 g or 200g. Readability is 0.1mg. The 120A, 160A and 200A balances also feature a capacity- or tare-availability indicator.
Circle No. 101 on Reader Service Card.

- Specially designed for the electrophoresis of nucleic acids on horizontal agarose gels, the GNA-100 'mini-submarine', and GNA-200 'submarine' from Pharmacia are injection moulded, state-of-the-art units. Gel trays and lids are made of UV-transparent material; electrodes are robust titanium-based rods and a wide selection of gel combs is available.
Circle No. 102 on Reader Service Card.

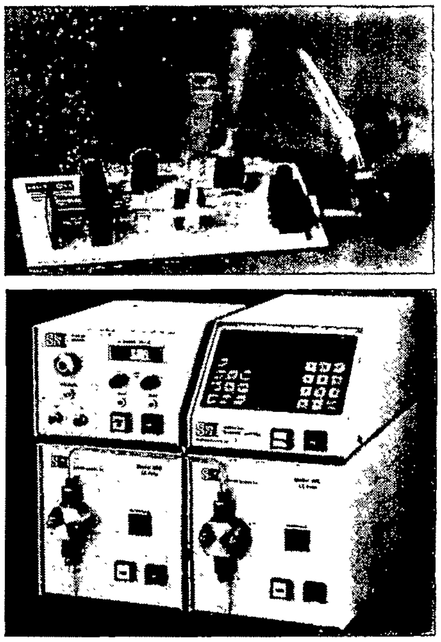
- Clontech's Lamda (λ) gt11 immunoscreening kit (CLIK) offers well-characterized control components for screening λ gt11 expression libraries with antibody probes to assure that the proper conditions for antigen detection are used. CLIK includes λ gt11 chicken ovalbumin clone, λ gt11 phage, rabbit anti-ovalbumin serum, and biotinylated goat anti-rabbit IgG. The detection of bound primary antibody using biotinylated anti-IgG is extremely sensitive. False positives are rarely found.
Circle No. 103 on Reader Service Card.

- The Nicool LM 10 manufacturerd by the Harris Manufacturing Co. is designed for freezing biological specimens in cryotubes or straws. Manually operated and using liquid nitrogen as a refrigerant, and Nicool LM 10 is approximately 23 inches tall and 10 inches wide. Samples are placed at a specified level above the liquid nitrogen and freezing rates are obtained proportionately to the speed of the fan. Specimens can be plunged into the liquid nitrogen without opening the chamber. The electrical service is 110 volts.
Circle No. 104 on Reader Service Card.

- Scientific Systems, Inc. produces a low cost HPLC gradient system, featuring the Model 230 gradient control, the Model 210 Guardian, and two Model 200 LC pumps. Built around SSI's proven single-piston rapid refill pump, this system offers the chromatographer a sophisticated analytical instrument at low cost. The Model 200 delivers precise flows from 0.05 to 9.99 ml per min at pressures up to 6,000 p.s.i. and includes a compensation control that adjusts for the compressibility variations of different mobile phases. The Guardian enhances the operation of the pumps, acting as a pulse damper, a pressure monitor, high and low pressure limit circuits and a prime purge valve. The gradient control is a microprocessor-based unit designed to interface directly with the Model 200 (or other pumps having frequency-controlled flow rates).
Circle No. 105 on Reader Service Card.

- Based on the stopped-flow technique, the Hi-Tech SFA-11 rapid kinetics accessory reduces the fastest reaction half-life measurable with a UV/Vis spectrophotometer or spectrofluorimeter from several minutes to well under a second. Two precisely thermostatted 200μl shots of reagents can be readily mixed to fill the observation cell in less than 20 ms and thus half-lives down to less than 0.5s may be measured. The potential thermostatting range is 5 to 80°C. The observation cell can be fitted in seconds to any instrument that accommodates 10 mm cells/cuvettes. It has both 2 and 10 mm optical pathlengths selected by rotating the cell through 90° in the cell holder.
Circle No. 106 on Reader Service Card.

- The Microsyn ultrasonic processor is designed specifically for high intensity work in small volumes offering rapid powerful disruption of 250 μl to 10ml of material. Stable high-intensity power is generated at the titanium probe tip by a PZT crystal piezoelectric converter. The standard probe is lightweight with the lower 100 mm maintained at 3.2 mm diameter for insertion into long narrow sample tubes. Interchangeable probe tips offer 4.8 mm diameter for larger volume processing and a subminiature 2.4 mm diameter for delicate micro work. Power is supplied to the probe via a flexible lead connected to a compact free-standing generator module allowing the probe to be used on the bench or built into a processing system if required. The Microsyn ultrasonic processor is produced by Life Science Laboratories.
Circle No. 107 on Reader Service Card.



The Hi-Tech rapid kinetics accessory (top) and the SSI HPLC gradient system.

- A new compact radioisotope camera for the visualization of radioactive distributions of tritium and carbon-14 labelled compounds on TLC and paper chromatograms is now being produced by Birchover Instruments Ltd of Letchworth. The instrument uses a high resolution scanning spark chamber detector to produce a Polaroid print approximately ⅓ full size of the radioactive separations with exposure times of between 20 to 120 min, reducing considerably the evaluation time as compared with autoradiography which would require 3 to 21 days for a comparable result. A print projector for projecting the Polaroid print back so that radioactive areas can be quickly marked out on to the original radiochromatogram is an integral part of the bench top instrument.
Circle No. 108 on Reader Service Card.

- Imperial Laboratories (Europe) Ltd. of Salisbury has developed a serum-free lymphocyte culture medium for cytogenetics. This medium, Iscove's modification of Dulbecco's MEM, has the folic acid level reduced from the normal 4.00mg to 0.01mg per litre. Imperial Laboratories will undertake the production of cell culture media to customers' specifications in addition to supplying their range of standard media and sera. The medium was developed in conjunction with the Wessex Regional Cytogenetics Unit at Salisbury General Hospital.
Circle No. 125 on Reader Service Card.

● Ten purified homologues of tunicamycin are now available from Boehringer Mannheim Biochemicals. Each homologue exhibits a different degree of inhibition of glycosylation and overall protein synthesis. Thus, using a purified homologue rather than a standard commercial preparation of tunicamycin (mixtures of these homologues), achieves a much greater precision of inhibition. The levels of inhibition of protein synthesis by tunicamycin homologues and glycosylation are dependent on the system and growth conditions. Selection of the homologue with the desired inhibitory effects will be largely empirical.
Circle No: 109 on Reader Service Card.

● From LKB Instruments, Inc., comes a new pamphlet on the bioluminescent assay of NADH and NADPH. Application Note 506 offers a useful summary of the current state of the art, plus two generalized bioluminescent assay protocols, and a selected bibliography of applications in enzyme and metabolite analysis. The light produced by these luminescence methods is from two purified forms of bacterial luciferase specific for either NADH or NADPH. Measurement of light is simple as the quick flash problem has been solved by the monitoring reagents. In the applications section 14 dehydrogenases and other enzyme references are listed.

CRITICAL MISTAKES
made in buying fermentation equipment
and what you can do to avoid them
Avoid These 19 Critical Mistakes When Buying Fermentation Equipment
1. Lack of a Recirculating System

How to avoid the 19 critical mistakes in buying fermentation equipment

Make one mistake and you can have problems that include inadequate process control, permanent operator inconvenience and costly downtime.

Now NBS has published a comprehensive review of the problems and pitfalls that await the unwary buyer of industrial fermentors — and some very practical suggestions to help avoid them.

Called *19 Critical Mistakes Made in Buying Fermentation Equipment and What You Can Do to Avoid Them,* this practical guide is available without charge.

Send for your free copy today. New Brunswick Scientific Co., Inc., P.O. Box 986, Edison, NJ 08818. (201) 287-1200 or (800) 631-5417.

Circle No.13 on Reader Service Card.

● The Bio-Rad Bio-Gel TSK SP-5PW cation exchange HPLC column offers the advantages of high resolution, high sample loads, and high recoveries of biological activity in protein and peptide analysis. Unlike silica-based ion-exchange HPLC columns, the SP-5PW column, with its resin based packing, permits a *p*H operating range of 2—12. This wide *p*H range gives flexibility in optimizing protein separations and simplifies column cleanup procedures. Either acid (0.1M HCl) or base (0.1M NaOH) washes may be used to clean the column. The 1,000 Å pore size of the SP-5PW matrix enables the column to separate proteins with molecular weights as high as 10^6. The column has a capacity of 1-5 mg for the protein of interest.

A new system for applying samples for electrophoresis—the Practiga from Shandon

● The Shandon Pratiga system is a new application system for electrophoresis, designed for separations on cellulose acetate membranes including serum proteins, haemoglobins, lipoproteins and isoenzymes. The Pratiga system performs up to 48 separations in one run using 'Dispocards' which 'stroke' the sample onto the applicator ensuring even deposition everytime. The sample is applied in a long narrow rectangle, regarded as the best geometric form for optimum scanning and sample evaluation. There are no capillary effects or globules of sample on the side of the applicator avoiding the inherent design faults of conventional wire-type applicators.
Circle No. 112 on Reader Service Card.

● World Precision Instrument Inc.'s new S7000A modular microelectrode system combines proven technology with latest advances. Features include ultra-stability, low noise, and ± 100 volt compliance. Mainframes are available in either single or four channel designs, and modules are available for ionophoresis, electrometer, and a voltage/patch clamp. Each module is supplied with one probe of the end-user's choice.
Circle No. 113 on Reader Service Card.

- Tissue, organs, tumours and coatings can be rapidly disintegrated using Heat Systems-Ultrasonics' ultrasonic debrider, and the resulting homogenate is removed in the same operation. Liquids such as water, saline, acid, or solvents travel down the centre of the needle and flood the tip. Intense ultrasonic energy disrupts any solid matter near the tip, even bone. Simultaneously, the fluidized mass or tissue is sucked through the needle and exits at the rear of the probe. Both ultrasonic energy and liquid flow are controllable. The probe is 6 inches long and available in three tip diameters: 3/8 in, 1/8 in, and 0.010 in.

Circle No. 114 on Reader Service Card.

- A new 5 mm Radial-Pak cartridge with Waters Nova Pak C$_{18}$ packing for high sensitivity HPLC analyses is now on the market. The cartridges allow HPLC analyses with the efficiency (100,000 plates per metre) to separate acids, neutrals and amines within the same mixture. Used with Waters Radial Compression Separation Systems (RCSS), Waters Radial-Pak cartridges are low cost, flexible-wall HPLC 'columns'. When radially compressed in a RCSS module, the cartridge provides a stable column bed which results in longer life, typically three times longer than a conventional steel column. Nova Pak C$_{18}$ is a 4-μm spherical packing featuring an exclusive bonding end-capping process which provides a stable and durable stationary phase for wide selectivity of all compound classes.

Circle No. 115 on Reader Service Card.

- The Miniultrasart from Sartorius is a self-contained ultrafiltration module with a 20,000 molecular weight cutoff membrane. The Miniultrasart offers high flux rates and long service life and is specially suited for depyrogenation of water and other liquids, and concentration/fractionation of macromolecules.

Circle No. 116 on Reader Service Card.

- A new bulletin from Bio-Rad describes 7 carbohydrate analysis HPLC columns, each specially tailored to separate a specific class of carbohydrate, and discusses ways to optimize separations with each column. Topics discussed include selecting the proper column, solvent selection, organic modifier concentrations, and optimizing column temperature and flow rate.

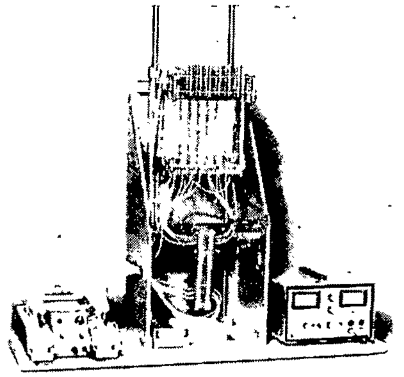
Liposomes

A new laboratory instrument (LIPOPREP®-GD-1) is available for the **reproducible** preparation of extremely homogeneous, unilamellar liposomes of controllable size. The instrument permits the **simultaneous use of five different lipid mixtures** and provides extensive versatility. Applications range from membrane reconstitution, remodelling of cellular functions, liposome drug delivery systems, microanalysis of drugs and metabolites, to antibody targeting, clinical diagnostic assays, and genetic engineering.
For details write to:
DIANORM-Geräte, P.O. Box 126, D-8 München 65, FRG.



The Isoprep isoelectric focusing apparatus.

- The latest LC 5001 amino acid analyser, available from Astra Scientific International, features a high pressure fluid delivery/sample injection system for efficient column packings and an automatic reaction coil flush for emergency and scheduled instrument shut-downs. A microprocessor controls the entire analytical protocol with eight user-defined programs. Chromatographic separations require only 45 min for protein hydrolysates and 95 min for biological fluids. An adjustable temperature-gradient profile fine tunes chromatographic separations, and standard features include dual HPLC pumps, a refrigerated compartment for storage of samples, eluents, and reagent, dual-channel photometer, and dual-channel recorder.

Circle No. 118 on Reader Service Card.

- A new line of plastic, disposable serological pipettes featuring continuous dispensing tips for accurate fluid delivery is now available from Bellco Biotechnology. Made of high clarity polystyrene with crisp, fine line graduations and large numbering for easier reading, the pipettes' pulled tips provide smooth internal wall surfaces which cannot trap and hold back fluid when dispensing. They are calibrated for accurate delivery with dispensing accuracy rated within ±2%. Bellco plastic serological pipettes are compatible with all standard pipetting devices, and are available in four sizes to suit most laboratory needs. The four sizes are: 1 ml with 0.01 ml graduations; 2 ml with 0.01 ml graduations; 5 ml with 0.1 ml graduations; and 10 ml with 0.1 ml graduations. All are provided with cotton plugs and packed in sterile individual wrappers, or sterile canister packs.

Circle No. 119 on Reader Service Card.

- The Hamilton Microlab 1000 diluter/dispenser is capable of carrying out standard curves with up to 10 diluting steps in one program. In addition, it has the following optional functions: serial diluting, serial pipetting, multiple pick-up, serum distribution, diluter function, double diluter, dispensing and repetitive dispensing. Up to 50 programs can be stored and retrieved. On the sample side syringes of 50μl to 5 ml and on the diluting side from 50μl up to as much as 25 ml can be used as required.

Circle No. 120 on Reader Service Card.

- The Medical Products Division of Ionics, Incorporated has introduced a new recirculating isoelectric focusing system for separation of proteins. IsoPrep systems can be used to separate synthesized peptides and enzymes on a preparative scale and is scalable for production of genetically engineered proteins. The IsoPrep system separates proteins of close *p*I's under the influence of applied d.c. electrical current. It uses porous membranes to form multiple compartments, each with a different *p*H. The membranes prevent convection but allow the proteins to migrate freely until they reach a channel with *p*H equal to their respective isoelectric points and concentrate there to be collected.

Circle No. 121 on Reader Service Card.

- The Nytran membrane from Schleicher & Schuell is a modified, positively charged nylon-66 solid support medium for use in nucleic acid and protein transfers. The new membrane offers a high binding capacity that allows for complete immobilization of all samples. It gives low backgrounds and has the ability to bind nucleic acids at low molecular weight, making it especially suited for electrophoretic transfers. It is also suitable where re-probing is necessary.

Circle No. 122 on Reader Service Card.

- Tresyl-activated Sepharose 4B is a pre-activated affinity medium for the immobilization of small ligands and proteins. The new medium can accomplish easy and reproducible coupling through both thiol and amino functional groups. Coupling capacity is affected only by the nature of the ligand, the temperature, and the *p*H. Since the active coupling groups of this affinity medium are stable to hydrolysis, unused swollen gel can be stored for at least one month. Tresyl-activated Sepharose 4B, from Pharmacia is supplied in 15g pack sizes which yields approximately 60ml of gel.

Circle No. 123 on Reader Service Card.

- Dionex's new amino acid analysis systems are claimed to bring more speed, reliability, and simplicity to amino acid analysis. Based on a new pellicular cation exchange resin, it combines the specificity of ion-exchange chromotography with the speed and simplicity of reversed phase HPLC methods. Conventional cation exchange resins require long separation and equilibration times (60–90 min total analysis time). Reversed phase methods, while offering fast run times, suffer from sample matrix interferences, instability of pre-column derivatives and short column life. Dionex's new cation resin operates at ambient temperature in a completely non-metallic system using very dilute, non-citrate eluants. Hydrolysate analyses are completed in less than 30 min.

ANNOUNCEMENTS

Awards

The **Medical Research Council** UK annually awards Senior Research Leave Fellowships and Senior Clinical and Non-Clinical Fellowships. For further details contact the Grants Section, MRC, 20 Park Crescent, London W1N 4AL, UK.

Applications are invited by the **International Foundation for the Promotion of Nutrition Research and Nutrition Education (ISFE)**, Zug, Switzerland for the 1985 ISFE Prize on research into new approaches to the prevention and/or treatment of obesity. Conditions of entry for the Sfr. 15,000 award are obtainable from the President of the Foundation, Professor Dr J.C. Somogyi, Niedelbadstrasse 82, 8803, Ruschlikon, Switzerland.

The **International Association of Gerontology** has announced that the 2nd Sandoz Prize for Gerontological Research (worth 20.000 SFr) will be presented in July 1985. Further information from Dr Leo Abisch, International Association of Gerontology "Sandoz Prize for Gerontological Research", Box 4043, CH-4002 Basle, Switzerland.

The **Scientific Council of the International Centre for Theoretical Physics**, Trieste, Italy is again offering an annual prize of US $1,000. For further information contact the 1984/1985 Prize Committee, International Centre for Theoretical Physics, PO Box 586, 34100 Trieste, Italy.

For details of the International Research Awards offered by the **World Population Council** on Determinants of Fertility in Developing Countries, contact the Program Manager, The Population Council, 1 Dag Hammarskjold Plaza, New York, New York 10017, USA.

The **National Science Foundation** (US) Alan T. Waterman Award Committee has issued a call for nominations of candidates for its tenth annual award intended to give recognition to outstanding US researchers under 35 in any field of science, mathematics or engineering. Additional information from the Executive Secretary for the Committee, Mrs Lois J. Hamaty, NSF, Washington D.C. 20550, USA.

Appointments

Mr Roger Courtney has been appointed as head of the Technology and Innovation Directorate of the Energy Efficiency Office the Department of Energy, UK.

Dr K.J. Treharne, Head of the Plant Sciences Division at the Long Ashton Research Station, Bristol University, is now to take over as Director; he has also been appointed to a Chair and the Headship of the Department of Agriculture and Horticulture within the University.

Alan Watson, Reader in Particle Cosmic Physics in the Department of Physics and Dean of the Faculty of Science at Leeds University, has been appointed a Professor of Physics at the University.

Mr Don Metz, currently Deputy Secretary with the Department of Territories and Local Government in Canberra, Australia, has been appointed as the new Director General of the Commonwealth Agricultural Bureaux — the first Director not to be resident in the United Kingdom.

Ms Gill Glass has been appointed Managing Director of Bachem UK, the British branch of Bachem Inc., USA.

Mr F. Edward Gustafson and **Mr William F. Hendershot** have been elected as vice-presidents of Miles Laboratories Inc., Indiana, USA.

Dr. Muroni, currently president of the University Corporation for Atmospheric Research in Boulder, Colorado, has been nominated to a six-year term as a member of the National Science Board, Washington D.C., USA.

Dr. Charles Elachi has been named manager of the Earth and Space Sciences Division of the Jet Propulsion Laboratory, NASA, California.

Meetings

22-26 October, **European Wind Energy Conference and Exhibition**, Hamburg, FRG (H.S. Stephens & Associates, European Commercial and Technical Conferences, Agricultural House, 55 Goldington Road, Bedford MK40 3LS, UK).

29 October-1 November, **Second International Conference on Computers in Science**, Washington D.C., USA (Computers in Science, Scherago Associates, Inc., 1515 Broadway, New York, New York 10036, USA).

14 November, **Meeting on High Complexity Displays**, London (The Meetings Officer, The Institute of Physics, 47, Belgrave Square, London SW1X 8QX, UK).

15 November, **Seminar on Plan for Computer Integrated Manufacturing**, London, UK (The Manager — Conferences and Exhibitions, The Institution of Production Engineers, Rochester House, 66 Little Ealing Lane, London, W5 4XX, UK).

15-17 November, **3rd Epileptology Meeting — The Epileptic and His Family**, Coimbra, Portugal (Dra. Margarida Santiago, Clinica Neurológica, Bloco Hospital de Celas, H.U.C. 3000 Coimbra, Portugal).

20 November, **Paper on Technological Change — The Effect on People at Work**, London (The Manager — Conferences and Exhibition, The Institution of Production Engineers, Rochester House, 66 Little Ealing Lane, London W5 4XX, UK).

22 November, **Hockley Memorial Lecture on Communications and Propaganda**, London, UK (Secretary, Institute of Scientific and Technical Communicators, 17 Bluebridge Avenue, Brookmans Park, Hatfield, Hertfordshire AL7 9RY).

26-28 November, **2nd International Conference and Exhibition on New Technology and the Food and Drink Industries**, Bristol, UK (Mr David Jones, New Technology & the Food & Drink Industries Conference, Brintex Limited, 178-202 Great Portland Street, London W1N 6NH, UK).

27-28 November, **11th Mammalian Molecular and Biochemical Genetics Workshop**, London, UK (Dr G. Bullfield, Genetics Group, AFRC Poultry Research Centre, Roslin, Midlothian EH25 9PS, UK).

4 December, **International Conference on Hybridomes**, Paris, France. (INNOBIO, Scientific Association for Biotechnology Advancement, 26 Rue Guynemer, 75006 Paris, France).

17-19 December, **Annual Conference of the Society for Research into Higher Education**, London (SRHE, University of Guildford, Surrey GU2 5XH, UK).

3-5 January, **2nd International Conference on Clinical and Basic Factors Influencing Bone Growth**, Los Angeles, USA (Prof A.D. Dixon, School of Dentistry and Medicine, Dental Research Institute, Center for Health Sciences, University of California Los Angeles, Los Angeles, California 90024, USA).

12-16 January, **Keystone Summit on Allergy, Immunology, Pulmonology, and ENT**, Colorado, USA (Ms Helga Cole, National Jewish Hospital and Research Center/National Asthma Center, 3800 East Colfax Avenue, Denver, Colorado 80206, USA).

14-15 January, **2nd Annual International Symposium on Sample Preparation and Isolation Using Bonded Silicas**, Philadelphia, USA (Mr Lane Yago, Symposium Coordinator, Analytical International Inc., 24201 Frampton Avenue, Harbor City, California 90710, USA).

21-22 January, **Symposium on Pediatric Pharmacology**. Ahmedabad, India (Professor S.M. Mansuri, Chairperson, Department of Pharmacology, B.J. Medical College, Amedabad 380016, Gujarat, India).

22 January, **Meeting on Radiological Protection Measurements and Their Traceability**, London (Prof. J.H. Martin, Programme Committee Secretary, Department of Medical Biophysics, Blackness Laboratory, University of Dundee, Dundee DD1 4HN, UK).

18-21 February, **International Conference on Health Hazards and Biological Effects of Welding Fumes and Gases**, Copenhagen, Denmark (Mr Richard M. Stern, WHO/EURO, 8 Scherfigsvej, DK-2100 Copenhagen Denmark).

22-24 February, **International Symposium on Conceptual Issues in Environmental Archaeology**, Oxford, UK (Conceptual Issues in Environmental Archaeology, Department of Geography, University of Strathclyde, Livingstone Tower, 26 Richmond Street, Glasgow G1 1XH, UK).

Causes of the British disease

Economists are once more glooming about the British economy, but looking for remedies in the wrong places.

JUST over a decade ago, the then Conservative British Government under Mr Edward Heath took fright that the unemployment rolls appeared to be growing inexorably and an inflationary budget was hastily put together out of season. There was hardly time to tell whether its intended effect — the creation of jobs — would have become reality, for the Heath Government was voted out of office after a bruising confrontation with the British coalminers' union. Now, with another Conservative Government in office, there is again a miners' strike (not fully effective), the pound sterling is trading more cheaply against other currencies than ever before and, this time, unemployment is twice what it was when Mr Heath took fright. Inevitably, people wring their hands in anxiety, even despair. What has gone wrong? And what can be done to put things right?

Most answers to these questions are political, usually in the partisan sense, and that, in the long run, is the language in which they will have to be answered. But there is also an sense in which the problem of the British economy is a model, not an especially uplifting model, for the way in which economic systems should be managed in times of rapid technological change. The curious feature of the British example is that it has been fully analysed and thoroughly discussed for at least the past forty years (since the end of the Second World War), and that even now, nobody is quite sure of what should be done. The government of the past five years believes that sound money is an essential part of any solution (which is probably true), and recently has taken to saying that a more flexible job market would also help (which is probably also true, but only up to a point). The chief opposition party, on the other hand, says that the chief need is to create more jobs, and is plainly envious of the way in which deficit financing of the Reagan Government's operations seems to have gone hand-in-hand with a revival of economic activity in the United States. The obvious difficulty is that the objectives at which the political parties have set their sights may be parts of a solution to the problems that afflict the British economy, but cannot be the whole of one.

Changes

That the post-war decades would be times of rapid change was apparent from the outset. That they would also be decades of rapid social change was also obvious, and was foreseen. The agenda for most speculations about what may happen to Britain was set in the five hectic years to 1950, a period of unprecedented and unmatched change. While voluntarily giving the notion of being the hub of an empire, the British embarked on two enlightened schemes — universal high-school education and a social security system and a health service to go with it — embodying the principle that bad luck (including ill-health) should not overwhelmingly determine the conditions in which people lived and died. During the same five years, several major industries (railways, coal, electricity generation and supply) were nationalized. (Steel and water came later, telecommunications were an outgrowth of Rowland Hill's Victorian Post Office and will be half-turned over to the private sector only next month.) It tends now to be forgotten, even in Britain, that from this earliest post-war period, government committees were repeatedly forecasting desperate shortages of trained technical people, and pleading that something should be done about the scale as well as the quality of technical education.

In retrospect, this heady period of social and administrative change was lived through with too little calculation of what the costs might be. Throughout the 1950s, while economic growth picked up, taxation grew even faster, with the result that a succession of Conservative governments presided over the personal impoverishment of most of those who had voted them into power. This was nevertheless a period of great optimism about the way in which technology would soon make Britain prosperous again — nuclear power would be dirt cheap, civilian jet airliners would fill the skies and there would even be thermonuclear power for succeeding decades to enjoy. The truth became plain only in the winter of 1962–63, when much of Britain went without electricity for weeks on end because the weather was appalling and the demand could not be met. There had already been the Italian miracle to remind the British how easily pride of place in some economic league table can be lost by erosion at the rate of one or two per cent a year. In the circumstances, it is only natural that the Wilson Government of 1964 should have promised prosperity by stimulated technological revolution — and that it should have failed because the money supply ran away from it.

Mistakes

Throughout this now long period, two categories of mistakes have been consistently perpetuated. First, in spite of the lip-service paid by governments of all colours to the importance of technical education as a basis for the prosperity of the modern state, too little has been done to turn the dictum into a reality. Qualitatively, the system has hardly changed in half a century. Young people are still required to choose at high-school the directions in which they will follow intellectual pursuits, with the consequence that many of the most able people follow careers which are only peripheral to present needs, while those who take the technical route have a lopsided education. Now, half a century later, there are signs that this may change. Quantitatively, however, there is great confusion. The present happens to be a time when there are obvious shortages of technical skills, and of general engineering knowledge, but there have as often been times when British governments and their advisers have been willing to leave what they considered well alone. In the circumstances, it is unremarkable that those technical people who work in industry are badly rewarded and undervalued. The common wry comment, that Britain is skilled at invention but poor at exploitation, is too often considered an entirely unconnected circumstance.

The other consistent mistake is the assumption, to which all governments are prone, that there are some features of the working of an industrial economy that are best decided by civil servants, not by those who earn their livings in industry or even by market forces. The most memorable follies of this kind date from the 1960s, when the Wilson Government embarked on schemes for cementing mergers between successful and less successful companies when it would have been cheaper, and simpler, to let the latter go to the wall. The curious circumstance is that similar transgressions of good sense occur even under the present government, which is almost un-British in its belief that business failure is merely the other side of the coin of success. Only two weeks ago, the Bank of England saved from bankruptcy a bank that should have been allowed to go to the wall. The same government is doing everything it can to encourage the growth of a few high-technology sectors without recognizing that they are unlikely to succeed unless there is a climate in which intermediate technology can also prosper. But as if to show its even-handedness, the government also goes to great trouble to ensure that its chosen sunrise industries fall flat on their faces needlessly. Thus it is that the two most experienced operators, Rediffusion and Visionhire, last week pulled out of the nascent cable industry, the brave new industry of 1982, because the terms of operating licences have been made unduly onerous.

The consequences of all this are evident. The free market in manufactured goods and value-added services is both hamstrung and feather-bedded. Why should the labour market be singled out for exceptional efficiency, with all the political trouble (and inequity) that would cause? But the civil service, acting as proxy entrepreneur, makes mistakes whose cost is never counted, but which can be measured by the collective impoverishment. But these are the circumstances in which, in a mobile world, people who think they can better themselves elsewhere are up and off. The cost to Britain of the shiploads of those who have left for good, convinced that Britain has nothing much to offer, is incalculable.

It is in the circumstances no wonder that the word has got about that Britain is not serious about its talk of joining the modern world. What sense can it make that a government seeking to sponsor a new industry should cripple it with artificial conditions that prevent it from being viable? Or that it should delegate decisions such as whether there should be another nuclear power station in Britain, not to the nationalized industry that would build and operate the plant, but to a one-man tribunal (with two advisers) sitting daily in Suffolk for the past two years? Would it not be better that the government should tackle the problems that nobody else has the power to tackle, such as the reform of public education? And should it not from time to time make speeches that give some hint that it is not entirely overwhelmed by the despondency about the future which, for want of evidence to the contrary, must be the general conviction. ☐

Argument too formal

The US National Academy has a new journal on public policy, which deserves to succeed.

AFTER more than a decade of introspection, the National Academy of Sciences in Washington has published the first issue of its journal concerned with the general implications of its members' professional work. *Issues in Science and Technology* is as handsome a publication as would be expected, given both the sources (the National Academy of Engineering and the Institute of Medicine are also partners in the venture) but also the ambition — to provide a regular (quarterly) commentary on important issues and related public policies that will compare in influence with publications such as *Foreign Affairs*. The Fall 1984 issue deals with some of the issues certain to be recurrent themes in the years ahead — ballistic missile defence, the cost of health care and the regulatory impediments to the application of technical innovation (specifically, the introduction of air bags as safety devices in impacting automobiles). At $6.00, the first issue is a good read, or at least an interesting one.

What will follow next is, naturally, not necessarily determined by this first advertisement of what the academies have in mind. Next time, for example, there will be no need to reprint the article by Daniel Yankelovich, the social pollster, retailing a simple account of why public disenchantment with science and technology has been growing since the 1960s. (The influence of articles on this same theme has not, unfortunately, been recorded.) Arms control is, however, certain to be a recurrent theme, and the first issue includes a pair of opposing articles, by Dr George A. Keyworth and Dr Sydney Drell, on star wars and related matters. Most people will find this a valuable summary of influential opinions on the subject.

So haven't the academics been brave, venturing so far from academic ways? That is what the blurbs suggest. The trouble is that neatly counterbalanced articles are less a way of helping to form opinion than to inform it. If *Issues* is to win the influence it seeks, it will at some stage have to climb down off this fence, not so as to be partisan but to avoid the appearance of seeking equal time within every pair of covers. And it will have to carry regular book reviews, not just thumbnail sketches of them. But the enterprise is brave; we shall all be better off it it succeeds. ☐

Truth will out (if late)

The departure from the United States of a once-German rocket engineer is a chilling lesson.

THE surprising announcement last week that Arthur Rudolph, who designed the Saturn V rocket, had left the United States and given up his US citizenship to avoid deportation as a Nazi war criminal should be enough to convince the most dedicated pragmatists of the moral contradictions in the recruitment of Nazi scientists at the close of the Second World War. More than a hundred Nazi scientists and technicians were then whisked to the United States in an effort to exploit Germany's commanding expertise in rocketry at that time — and, perhaps of greater importance to the US military commanders who directed the operation, to prevent Nazi experts from falling into the hands of the Soviets, as many nonetheless did.

The United States was plainly eager to overlook the obvious fact that these scientists had, with no apparent moral qualms, fully supported and enthusiastically worked for the Nazi regime; scientists are always called upon to build weapons for their country during wartime, the easy rationalization went, and these scientists just happened to be in the wrong country. It was not their fault; they were just following orders. And, mass memory being what it is, few in the United States seem to have been genuinely troubled that their space programme was partly run by the men who built the V-2. A rare dissent was registered in the 1960s by satirical songwriter Tom Lehrer, who summed up the amorality of the rocket scientists with his biting irony, ascribing to Wernher von Braun the opinion that where the rockets came down was "not my department".

The Rudolph case offers a reminder that really should not be needed that Nazi Germany was not just another country at war. Rudolph's job as director for production of the V-2 made him not only a collaborator with the German war effort, but with the most enormous of the Nazi horrors as well. The workers in the underground factory that produced the V-2 were slave labourers and concentration camp inmates. Of the 60,000 prisoners who passed through the Dora-Nordhausen concentration camp adjacent to the factory, one-third died. The Justice Department now says that Rudolph "participated in the persecution" of these labourers, who were worked 12 hours a day, starved, forced to sleep on bare rock in the tunnels and beaten.

The United States Government did not require 40 years to discover these facts. Rudolph was interrogated by US Army investigators in 1947, on that occasion giving contradictory answers to questions about treatment of prisoners, ultimately acknowledging that he had witnessed the execution of 12 prisoners accused of sabotage. But only the establishment in 1979 of a special office within the Justice Department, charged with investigating suspected war criminals in the United States, seems to have led to the recent action against Rudolph.

There is another reminder in this story. As much as researchers (and, it seems particularly, university administrators) like to maintain that science is not to be judged by its "end use", there are exceptions. Scientific research is a neutral, amoral enterprise only in a free society, one with a democracy capable of exercising social judgement over the propriety of end uses. In the absence of such social judgement, scientists have an obligation to exercise a personal moral judgement, to think through the consequences of their actions. ☐

British research council

Science council looks for projects to cut

THE British Science and Engineering Research Council (SERC) decided at its council meeting last week that it must withdraw from some of the research fields it supports. The council has given itself until February to decide how the pattern of its activities should be reshaped. "Major acts of surgery" are on the cards, according to Professor John Kingman, chairman of the council, speaking after the council meeting.

By Kingman's account, the council is now at a "turning point" in its affairs. Since this time last year, when the British Government refused the request from the Advisory Board for the Research Councils (ABRC) to provide more money for research, Kingman says the council has seen trouble coming. While the total research budget has been formally indexed against inflation, Kingman says that for various reasons it is being eroded by several per cent a year.

Among the council's immediate difficulties is a demand by ABRC that it should contribute £7 million towards the cost of reorganization at the Agricultural and Food Research Council, which is having to close a number of institutes under financial pressure. Kingman says he is "bitterly disappointed" that no extra help has been provided on this account. But the council has also been further hit by a decline in the value of sterling in the past few months, and by improvements of some university salaries (to which many postdoctoral stipends are tied).

Kingman says that with this project, the choice is between uniform cuts across the board and "more radical decisions" that will entail pulling out of some activities. For much of the past year, a group of council members and officials has been considering what steps of this kind might be taken, and what the financial savings would be. One conclusion is that a decision to shut down an institution or to abandon a research programme will yield full savings only over a period of five years. This is why, Kingman says, the impending cuts are meant to increase flexibility only in the 1990s.

For the time being, nobody is prepared to guess what will be cut. At pains to forestall the rumour mills, Kingman last week emphasized that the period between now and February will be used for a re-examination of the research programmes supported by the council's four spending boards (responsible for nuclear and high-energy physics, astronomy and space, engineering and general science). Each board will be expected by February to have "gone back to square one", and to present a new case for its claim on council funds. Kingman says that at last week's council meeting, he asked for and was given an assurance by the four board chairmen that they accept the need for a radical reappraisal.

The task of listing projects and institutions that might be abandoned, and of working out the savings that may result, will fall on SERC officials overseen by a steering group appointed by the council. It seems to be accepted that there will be no time for full consultation with those affected before decisions must be made in February, although Kingman says that there will still then be a need for individual boards to choose between options that will have been presented to them.

This tight timetable, which may be changed, is conditioned by the need that the council should disclose to ABRC its spending plans by next April, at the beginning of the next financial year. SERC hopes that the Kendrew committee's recommendation on continued membership of CERN (the European Organization for Nuclear Research) will be available by February, but "if not we shall have to do our own study". Pulling out of high-energy physics would "be an easy option" but could not give the council the flexibility it needs — it would merely "buy time" for perhaps five years.

Kingman is not hopeful that significant economies can arise from changed relationships with other research councils. He considers that there should be a closer relationship between SERC and the Natural Environment Research Council, however, and that ABRC should give thought to British support for research in biology. Economies through European collaboration accrue only when partners have money to contribute to joint projects.

Although the British Government's allocation of funds for 1985–86 and thereafter could still be increased above the amount forecast last December, nobody seems to think it likely that there will be a last-minute change of heart. Kingman last week also complained that last year's agreement with the Treasury about compensation for the depreciation of sterling, which yielded £7 million out of a total shortfall of £10 million, would have to be negotiated all over again this year, perhaps this time unsuccessfully.

The council seems to be entirely serious in its intentions. Professor Kingman last week quoted ABRC evidence to a House of Commons committee in support of his estimate that SERC would be £70 million short by the end of the decade (in a budget then estimated at £280 million a year). He said nevertheless that he welcomed the strategy document from the University Grants Committee, promising increased selectivity if "the other half of the dual-support system were properly managed".

On the question whether the council could have made its decisions sooner, Kingman said the investigation of what might be done had started a year ago, but that council would then probably have been unable to accept the need for the tough decisions it had now, in worsened circumstances, recognized to be necessary.

John Maddox

Medical shoestring pared down

A FURTHER drawing-in of horns in support for academic research in Britain is forecast in a letter from the secretary of the UK Medical Research Council (MRC), Sir James Gowans, to vice-chancellors of British universities. The letter, published last week, says that the council has no choice but to reduce the funds available for meeting project grant applications in the coming financial year by 7.5 per cent. Programme grants, used for supporting longer term projects, sometimes of a more open-ended character, are to be reduced by 25 per cent, while the funds available for paying stipends to postgraduate students and trainees will be reduced by no less than 30 per cent.

The council's letter, an unusual advertisement of its financial problems, explains that part of the reason for the substantial cut in prospect is the contribution, of about £2 million, that MRC will be required to make to the cost of reorganizing the Agricultural and Food Research Council. But it seems that the extra cost of university salaries, which affect the council's budget for expenditure already agreed by increasing automatically the salaries of research fellows, will cost the council more than £1 million next year.

As might be expected, the council's letter says that these further economies are made with regret. It also says that if there is some alleviation in the financial position, perhaps because the government accepts its case that its budget should be increased, it may be possible to increase the sums available for next year.

The surprise is that the council should have gone so far as to say that its case for extra money has been urged on the government, in the persons of the Prime Minister, Mrs Margaret Thatcher, and the Secretary of State for Education and Science, Sir Keith Joseph, by the secretary of MRC and its chairman, Lord Jellicoe. From the evidence of the latter now published, the meetings were particularly joyless even as these occasions go.

John Maddox

US Congress sweeps up remaining bills

ASATs, agriculture and antitrust

Washington

AMONG the last-minute business that the US Congress completed before adjourning to hit the campaign trail was the resolution of three long-standing issues in science policy and arms control:

Antisatellite weapons

MOVED to act by the absence of any discernible leadership on this issue from the White House, Congress imposed its own moratorium on testing of the new US antisatellite device, a small nonexplosive rocket launched from an F-15 fighter. The Air Force has so far conducted only one test of the weapon, which on that occasion did not carry a warhead. (The warhead, which has been described as a "smart rock", technically the Miniature Homing Vehicle, manoeuvres into the target satellite and disables it simply by ramming it.) The congressional ban is on testing against a live target — seen as the critical step in proving the weapon.

Under the compromise finally worked out between the House of Representatives, which had wanted a one-year ban, and the Senate, which favoured only a requirement that the President should convey to Congress certain assurances that the testing was necessary, no tests are allowed before 1 March of next year. After that, and before tests can begin, the President will have to certify that tests are necessary to prevent harm to national security, that they are consistent with the anti-ballistic missile (ABM) treaty and will not irreversibly harm chances for negotiation of an antisatellite weapons (ASAT) limitation treaty, and that an effort is being made in good faith to negotiate such limitations with the Soviet Union.

The law also provides for a 15-day waiting period after the President's certifications, during which time Congress could presumably vote to extend the moratorium — although any such vote would be subject to the President's veto. And no more than three tests against a target will in any case be permitted during the 1985 fiscal year, which ends on 30 September 1985.

Technical or political reasons, or a combination of the two, have delayed the second planned test, which has been expected for some time. In this test, the weapon, with warhead, will be shot at an imaginary target in space. Rumour has it that this test will occur within the next few weeks.

The limitations passed by Congress are a small but nonetheless important step — it is the first time that Congress has legislated on arms control. Representative George Brown (Democrat, California), a principal sponsor of the moratorium, said the measure "provides a *de facto* arms control agreement" that buys time "to get negotiations back on track".

No limitations have, however, been imposed on the US Air Force's budget for procuring the weapons. Congress approved $74 million for that purpose. The research and development budget is $133 million.

Agriculture

THE catch-all appropriations bill passed by Congress, which will keep the government operating until the end of the 1985 fiscal year, includes a generous budget for the habitually impoverished competitive grants programme for agricultural research. Created in 1977 as a alternative to the formula-funding system — long criticized for its absence of peer review and its exclusion of non-land-grant colleges — the programme has been held to a mere $17 million by those in Congress — notably Representative Jamie Whitten (Democrat, Mississippi) — who saw it as a threat to business as usual.

This year, Congress agreed to $46 million, close to the $50 million requested by the administration. Efforts by Whitten to keep up the appearance of a budget increase while undermining its substance were, however, modestly successful. Within the $46 million is $7.5 million earmarked by Whitten for specific programmes, apparently transferred wholesale from "special grants" — congressionally-mandated research that the US Department of Agriculture has never cared for and which are finally being eliminated this year. Thus while the general area of plant sciences was voted an increase of $1.5 million from last year's $15 million, $1.7 million was set aside for special projects in soybeans, acid precipitation and alcohol fuels. A new area of "pest sciences" turns out to be devoted completely to three special projects, with $1 million apiece: studies of boll weevil, pine bark beetle and gypsy moth. And of the $4.5 million appropriated for a new area of animal sciences, $3 million is committed to special projects.

Real gains were, however, made in the creation of a new $20 million biotechnology area, with no strings attached. The human nutrition area will receive $2 million, as before.

The director of the competitive grants programme, Ed Kendrick, says that although the incorporation of the special projects into the programme will take some careful planning, all the money will be awarded on a competitive basis.

Most attention now will turn to the budget for the next fiscal year, due next February. The first substantial increase in competitive grants for several years is bound to whet the appetites of their advocates.

Requests for proposals in the new programme area will be announced in mid-November.

Antitrust exemption

HIGH-technology companies in the United States have been pressing for an exemption from antitrust laws that would allow them to collaborate on research without fear of landing in court. The inevitable comparisons with Japan were heard over and over again at congressional hearings least spring. Legislation signed by the President on 11 October confers a degree of protection upon such joint ventures, although it stops far short of the blanket exemption that industry had hoped for.

Under the principal antitrust statutes, a company engaged in anticompetitive practices can be sued by a competitor for three times the competitor's actual monetary damages. The bill just enacted limits that to actual damages in the case of joint ventures in research and development, so long as the companies entering into such collaborations disclose their activities in advance to the federal government.

The government will print a notice in the *Federal Register* listing the parties and a general description of their activities; although more specific information will have to be supplied to the government, those details will be protected against release to the public.

The theory behind the new law is that although joint ventures in research and development have never been illegal *per se*, the threat of triple damages has made companies overly cautious. And, in turn, companies involved in such ventures are likely to toe the line if they know that the Justice Department is keeping an eye on them.

The new law provides another protection for joint research and development ventures by allowing courts to award attorneys' fees to defendants who are the victim of frivolous lawsuits.

Whether the law will be the tonic to US industry that its high-technology advocates claim is questionable. For one thing, joint research and development ventures have almost never been the target of antitrust actions anyway. In the past 25 years, only four cases have been brought; and none of these questioned the joint collaboration *per se*.

The best known case was brought by the Justice Department against the major US auto-makers, which had collaborated on pollution control research (which was not illegal) but then allegedly conspired to delay the introduction of that technology. In another famous case, a photographic company sued over a joint research venture that Kodak had entered into with virtually all other photographic companies, excluding only the plaintiff in the case.

Stephen Budiansky

Carlsberg Foundation

Research rides on beer sales

SOME countries have natural resources; so does Denmark. It has beer. And Danish beer benefits science for, strangely enough, the United Carlsberg and Tuborg breweries are run by five professors for the profit of research. And since conservative Danes drink nothing but Carlsberg and Tuborg, and since the breweries have been investing effectively in breweries abroad (Britons now drink more Carlsberg than the Danes), the Carlsberg Foundation has been doing well.

In fact, the Carlsberg Foundation for Research has increased its spending by 20–25 per cent a year for the past four years, and it now disburses annually as much as the Danish natural sciences research council. A fair fraction of the foundation's money goes to the humanities, but that still leaves a fine sum for science, from astronomy to microbiology. Yet, says foundation secretary Niels Petri, most of the recent increases have been taken up in "supporting unemployed scientists". And future growth is threatened by new tax laws.

Beer also pays for the Carlsberg Laboratory, supported directly by the breweries as a tax-break, which is free to range (in style) over much basic agricultural and molecular biology. In the past, the laboratory was responsible for the first cloning of a microorganism (E. Christian Hansen's pure yeast cultures), S.P.L. Sørensen's concept of *p*H, Linderstrøm-Lang's concepts of protein structure and function and — they say — Schmidt's discovery of eel migration and Winge's discovery of sexuality in yeast. More recently, the laboratory did less well, but now in quite extraordinary new premises there appears to be something of a refermentation at the Carlsberg.

"Recruiting? We've never had to do any", says Carlsberg Laboratory director of physiology, Professor Carl von Wettstein. According to a Danish student, a scientist can get to work at the Carlsberg only "by invitation". The laboratory, however, has few permanent jobs. Of the 150 researchers at the laboratory at any one time, many will be postdoctoral people from abroad working on foreign money.

"But we get more results per kronor than any other institution in Denmark", claims von Wettstein. And the fact that he has to apply for outside money, from the European Communities for example, is proof that the laboratory is not over-generously supported, he says.

The only problem of working at the Carlsberg, say researchers there, is a strict requirement to publish in the house journal *Carlsberg Research Communications*, which has a circulation of only 400. But, says von Wettstein, the good work gets out anyway; the journal is critically refereed; it is not so affected by fashions as other journals; and it can report steps in major projects that take years to complete, as in the Carlsberg work on chlorophyll synthesis. "This was very fashionable in the 1960s, then everyone dropped it because it was too difficult. But we carried on and published in our journal."

In spite of acknowledged successes, some observers say the foundation could be more adventurous in the way it uses its funds. The five professors who direct it have considerable power to influence the directions of Danish science, but they usually walk in strict step with the research councils. Moreover, foreign beer sales are levelling off, and Petri expects the foundation's funds to level off next year, quite apart from possible tax changes aimed at a number of foundations somewhat less charitable than the Carlsberg.

Robert Walgate

Synchrotron radiation

THE French and West German governments have agreed to place the European Synchrotron Radiation Source (ESRS) at Grenoble, in the foothills of the French Alps, and not at Strasbourg as previously predicted by French government and scientific sources. This will put ESRS alongside the extremely successful high neutron flux beam reactor of the Institut Laue Langevin, and the announcement (last Friday) has been greeted with enthusiasm as making scientific sense.

Whether it makes political sense, however, is unclear. According to the announcement, ESRS will be a Franco-German facility; but the outline diagnosis of the synchrotron was done not just by France and Germany but also by the United Kingdom, Italy, Denmark, Sweden and Finland, two of which (Denmark and Italy) had put in firm site proposals.

Denmark has protested about apparent French hijacking of the project. All seven countries had been paying the costs of a study under the auspices of the European Science Foundation (ESF) to bring up ESRS, originally designed in 1979, to modern standards. The 300-page draft of the new design was sent to officials of the seven countries earlier this month, and a meeting of the ESRS intergovernmental programme committee (under ESF) is due to take place in Brussels tomorrow (Friday), ostensibly to discuss that design.

A French government spokesman on Monday was, however, unable to explain the relationship between the Franco-German ESRS decision and the ESF committee. Would ESRS be solely for the use of France and Germany? "France believes in creating a 'European space for research' " he said, quoting Prime Minister Laurent Fabius, "so ESRS will be open to all Europe". Robert Walgate

Genetic manipulation

Agency tries out regulations

Washington

THE US Environmental Protection Agency (EPA) last week formally announced its interim policy on field tests of microbial pesticides (*Federal Register* 49, 40659–40661; 1984). Citing a "higher degree of uncertainty in predicting ecological impacts" of microbial as opposed to chemical pesticides, EPA will in future require 90 days' advance notice of field tests of "genetically altered or manipulated" organisms, or of those not indigenous to the test area. Hitherto, field tests of pesticides on plots smaller than 10 acres have been exempted from the notification requirement.

Industrial companies seem pleased with EPA's efforts to regulate in this area. The Monsanto Corporation has already given notice of its intention to carry out field experiments that will be controlled under the new policy; Robert Conken, director of registrations for the company, said the rules would satisfy the public's demand for regulation without impeding research.

As expected, EPA will not require a formal "Experimental Use Permit" for every test. Under the new policy, companies will, however, need to provide EPA with complete information about the proposed test, including details of the ecology and physiological tolerances of the test organism, as well as a complete description of the manipulations performed and their expected results. The agency will also require proposals for monitoring any spread of the microorganism and evaluating potential adverse effects, together with methods for disposal of exposed materials. The test will be allowed to proceed if EPA raises no objection in the 90-day notification period.

There were, however, some questions raised by industry about the scope of the new policy. Conken asked how a company should determine whether an organism is "non-indigenous" and so within the new guidelines: would an organism that occurs naturally elsewhere in the same state, for example, be counted as indigenous? There is similar uncertainty about the meaning of "genetically altered or manipulated" — the question being whether organisms obtained through artificial selection, for example, are included. But many of the questions are likely to be answered quite soon, when EPA produces a policy statement that will also cover releases of genetically-engineered or non-indigenous organisms other than pesticides. The agency plans to use the existing Toxic Substances Control Act for non-pesticides (see *Nature* 23 August, p.613). And EPA officials stress that no decisions in this area should be regarded as final: the agency is by its own admission feeling its way, and comments are invited on how the regulations should be improved. **Tim Beardsley**

US space station

Anxieties abound in Europe

THE British Government is steeling itself for a decision on whether or not Britain should participate, at an estimated cost of £40 million a year, in the development of the US manned space station. But it can expect little direct financial help from British industry, which considers that investment in such a long-range project is a matter for the government. Such was the general feeling of participants at a symposium staged two weeks ago by the Department of Trade and Industry (DTI) to sound out the views of industry and science.

Another first for Britain—the only nation to send an I.O.U. into space!
S.E.R.C.

For the British Government, part of the problem is that space spending will have to increase because of the demands of the European Space Agency (ESA). The agency's Horizon 2000 study earlier this year recommended an increase of the science budget by 7 per cent a year over five years. Britain now contributes £13 million a year, based on the Gross National Product. Failure to pay the proposed 40 per cent increase by 1990 could exclude Britain from a series of ambitious ESA projects, including a new X-ray observatory, a submillimetre orbiting telescope and a probe to return samples from a comet or asteroid.

The need for extra cash will embarrass the Science and Engineering Council (SERC), whose fixed budget is already under strain and which is already considering whether to strengthen support for general research at the expense, for example, of high-energy physics. Ironically, SERC finds itself facing the prospect of a shortfall in space funds at a time when an internal review group, under the chairmanship of Sir Mark Richmond, is about to recommend greater use of ESA by Britain's space scientists.

By the time science ministers meet in Paris to discuss the long-term goals of ESA, in January next year, Britain's European partners will expect a reaction to both new demands for funds. But, before then, the British Government needs to be convinced of the economic potential of a space station. At the DTI symposium, PA Technology attempted to do just this, presenting the results of a study on the industrial processes that stand to benefit from a microgravity environment. It pinpointed two principal areas: the fabrication of defect-free semiconductor crystals and the preparation of extra large protein crystals. PA Technology says that the latter could benefit the enzyme business by allowing molecular structures to be defined quickly and efficiently.

Even so, British high-technology companies are sceptical of the benefits and of the speed with which they would emerge. The cost of the space station is estimated at $8,000 million (1982 prices); the United States hopes that 15–20 per cent will be contributed by Europe and Japan.

PA Technology also argued at the DTI symposium that participation in the space station would stimulate industrial research in areas such as robotics, computer design and materials manufacture. British Aerospace has endorsed this view, presenting, at the DTI symposium, specific plans for an unmanned platform, launched by the US shuttle, to which Britain might contribute 40 per cent of the cost. This plan would complement rather than duplicate the US manned space station, says the company, which claims that the National Aeronautics and Space Administration has already responded enthusiastically to the suggestion.

Elsewhere in Europe, there are more subversive views. Strong bodies of opinion in West Germany and Italy are pushing for an independent European space station, perhaps to work in conjunction with a US platform. This idea, called Columbus, is being widely discussed within ESA and reflects a feeling abroad in Europe that greater autonomy is necessary. Buoyed by the successes of Ariane and Spacelab, many aerospace companies are eager to show that they can function independently of the United States.

The United States expects firm proposals for European collaboration in the space station by the end of 1985, and will want to know how the work would be divided between participating nations, which may include Japan and Canada as well as European states, acting either independently or in concert through ESA, by mid-1986.

Marcus Chown

UK Australian nuclear tests

Inquiry stirs fallen dust

ON 16 October, the president of the Royal Commission inquiring into British nuclear testing in Australia, Mr Justice James McClelland, urged that if the British Government wished to have its views accurately represented, it would be well advised to appear before the commission. The newly-installed British High Commissioner to Australia, Sir John Leahy, had earlier expressed concern about the recent public allegations that the British authorities had disregarded the safety of aborigines and atomic personnel.

The present official silence, Sir John said, must not be interpreted as tacit admission to the charges laid, that the decision to present evidence would be taken in London and that it would depend upon "how the commission goes about its business in future". Mr Justice McClelland replied that the Royal Commission could not be expected to forbid publication of allegations discomfiting to the British Government.

So far the allegations claim that unprotected servicemen flew sorties through radioactive clouds, that they decontaminated aircraft after the tests, that servicemen had buried the corpses of aborigines found on the range, that mentally-retarded civilians were placed in bunkers near a Maralinga blast in 1956 (see *Nature* **310**, 90; 1984) and that servicemen were used as guinea pigs (see *Nature* **309**, 199; 1984), a claim stressed by counsel for the British Nuclear Test Veterans Association.

On 3 October, the three royal commissioners also heard an account of the discovery and attempted decontamination of a family of four aborigines who, it was alleged, had camped for a few days in the Marcoo bomb crater seven months after the 1956 Maralinga blast, in apparent contradiction to a report in January 1983 of the same event by the Australian Ionizing Radiation Advisory Council (AIRAC). Servicemen who had witnessed the event were told by a British officer that disclosure would result in court-martial and possibly the firing squad.

The commission's charter includes investigation of the safety measures taken before, during and after the tests, whether health had been affected, and the nature and size of the devices tested in the twelve major explosions and an unknown number of "minor trials" known as Rats, Kittens, Ayres, Tims and Vixens.

Last week, the federal government refused a request from the Australian Nuclear Veterans for legal aid to challenge the credentials of royal commissioner Mrs Jill Fitch. A conflict of interest arose, they asserted, from her continued membership of both the commission and AIRAC, since it was criticism by Professor Charles B. Kerr's committee in May this year of AIRAC's treatment of fall-out data which led to the commencement of the Royal Commission.

The commission is due to report in June 1985 and has applied to the British Government to take evidence in Britain later this year.

Jeffrey Sellar

European telecommunications

Community looks at strategy

Brussels

AFTER years of dithering, the member states of the European Economic Community have agreed to work together to strengthen Europe's telecommunications market. Meeting in Luxembourg on 15 October, industry ministers adopted two recommendations constituting a first step towards a telecommunications strategy.

First, all ten Community governments are to ensure that national telecommunications administrations consult before introducing new services. (The United Kingdom, in the throes of selling off half its nationalized industry, was at the outset rather embarrassed, but has now fallen in line.) Contacts already exist through the European Conference of Post and Telecommunications Administrations (CEPT) set up in 1959, but new services put into operation from 1985 would have to conform to standards now being laid down by the developing network of European standards bodies.

Six million ECU (European Currency Units) or $4.6 million have been granted by the Community to these bodies for a two-year programme for 1984–85 to define and certify European norms in the telecommunications field. Equipment other than terminals, such as digital transmission and switching systems, would have to conform to common standards from 1986.

The second recommendation would throw open to all member states procurement of both conventional terminals (telephone apparatus for mains telephone use, PABX, ordinary teleprinters) as well as telematic terminals.

On switching and transmission equipment, and conventional terminal equipment for which there are no common specifications, the recommendation is that at least 10 per cent of the annual value of orders should be opened up for tender throughout the Community.

French pleas that the market should be opened to the full have been resisted by the European Commission, which is wary of risking a flood of components from both other member states and beyond, as well as scaring member states off a move it has taken them four years to make.

As a technical pioneer, and still the world's biggest exporter of first-generation telecommunications (telex, telephone), with a trade surplus of $2,000 million a year, the Community recognizes its industry is at a turning point: how to develop a second- and third- generation market in telecommunications which can stand up to Japan and the United States.

The Community at present controls a 19 per cent slice of the world telecommunications equipment market, but growth to the end of the decade is forecast to be slower than in the rest of the world (6–7 per cent as opposed to 8 per cent in the United States and Japan). The Community's telecommunications sector represents 2 per cent of the Community's gross domestic product which, with innovation, could grow to 10 per cent by the year 2000.

The Commission, however, is looking further ahead. Telecommunications are already reckoned to affect 55 per cent of value-added services and 62 million jobs; according to the Commission, investments in telecommunications could double the turnover of the European economy.

Under the Community's telecommunications programme, informally adopted by ministers last May, aid to finance telecommunications in ill-favoured regions could be drawn from the regional fund, the European investment bank and the new Community lending instrument (which is tailor-made to encourage investments in such conditions).

These schemes are likely to figure on the agenda of the next council of industry ministers on 20–21 November, when there will probably also be a decision on a programme of telecommunications research and development. Twenty-five million ECU a year over a five-year period has been proposed for Research in Advanced Communications in Europe (RACE), to be financed jointly by the Commission, companies and research institutes, much along the lines of the computer research programme Esprit.

Meanwhile, the Commission plans to set up a number of analysis and forecasting groups to look after the development of new services such as integrated digital networks, cellular radio-telephone services, videocommunications and wide-bank trans-national networks. At the October meeting, industry ministers also found an extra 11 million ECU to extend the 1979–83 programme on standardization in data processing for a further two years.

Anna Lubinska

US policies offend Europeans

EUROPEAN optimism about the future of the new telecommunications strategy, as of other new industrial research and development programmes, is marred by anxiety about the effects of high-technology export restrictions by the United States.

There is speculation that the US 1976 Arms Export Control Act and the 1979 Export Administration Act will be tightened up by the new Congress when it reassembles next January.

Existing controls, justified on national security grounds by the US Administration, are suspected of giving US companies an unfair advantage over others.

At the informal dinner following the Industry Council on 15 October, the soon-to-retire EEC Commissioner for Industry and Research, Vicomte Etienne Davignon, told national ministers that the European Commission intends to draw up an inventory of US measures to restrict high-technology transfer and to assess the consequences for economic and industrial development in the Community. The objective of the study, which will be ready in six weeks, is to make it clear to the United States that security considerations and continued European economic and industrial development are not mutually exclusive.

There is particular concern in Europe at some of the recent measures by the US Administration to restrict the transfer of technology and the dissemination of scientific information, including restrictions on foreigners attending defence- or industry-oriented meetings and conferences, on the dissemination of certain published information, on the transfer of technical data regarding participants at private conferences to certain countries, stricter conditions for foreign scientists applying for entry visas and broadening the base for classified information.

More recently in Belgium, the United States attempted to block the export of agricultural machinery to the Soviet Union by the Pegard Company, on the grounds that it could be converted for military aims.

Anna Lubinska

North Sea records

A NEW centre for the storage of North Sea drilling records and cores was opened in Edinburgh last week by the junior energy minister, Mr Alec Buchanan-Smith. The centre will provide public access to core sections for sampling and inspection. Any oil company granted a drilling licence must make records and cores available, but only after an interval of five years.

According to Mr Buchanan-Smith, the first nine months of this year have seen more exploration and appraisal than any previous year. One hundred and forty wells had been drilled in the North Sea by the end of September, compared with last year's record total of 128.

The new centre will be administered on behalf of the Department of Energy by the British Geological Survey (BGS). The tasks of the 55 staff will include the provision of inspection facilities for the 40,000 core samples now housed, of which 50 per cent have been released for access. The associated borehole logs are stored in microfiche form. Samples of cores may be removed for experimental measurements subject to the approval of BGS, which says that the number of requests for access average about three a week. Apparently demand increases as deadlines for new licence applications approach. The annual cost of maintaining the centre is £120,000.

Philip Campbell

Thermonuclear fusion

Europe from hand to mouth

THE 1982–86 budget of JET, the Joint European Torus for fusion research at Culham in Oxfordshire, is running out ahead of time. Planned to last 60 months, the budget will last for only 46, until October next year. The reasons are inflation (the 1982–86 programme was fixed at 1982 prices) and high maintenance costs at JET, including £250,000 to rebuild JET shock absorbers after an accident earlier this year.

Despite the economic crisis in the European Communities, which pay 80 per cent of JET's bills, there is little concern at Culham that the extra money will not be found. Community programme budgets never allow for inflation, says JET budget director Peter Kind, and it is always assumed that shortfalls will be made good in the next programme. Even if the 1985–89 programme (overlapping the first by two years), now before the council of ministers, is not agreed until next spring, JET accounts for 1985 could be balanced.

Mr Kind also has a contingency plan. Since operations began a year ago, JET has been short-staffed, so that there has been a squeeze on design time for the JET "extension to full performance" (neutral beam and radiofrequency heating, tritium handling equipment and so on). It has therefore been difficult to keep up the rate at which contracts have been put out to industry. Kind thinks it will be possible to let purchasing slip by a couple of months, particularly on items needed only some years hence.

The high maintenance and operating costs are exactly those predicted by the JET design team, but double what the council of ministers allowed in 1982. So JET can say "we told you so". "We had allowed 5 per cent of the capital equipment costs (excluding buildings) a year for maintenance", says Kind, but the ministers allowed only 2.5 per cent. But since JET began operations, there have been "10–15 requisitions a day for items from £50 to £5,000, from nuts and bolts to vacuum seals", reaching a total of around £10 million over a year, compared with JET equipment costs of £175–£200 million in today's values.

The largest item, the £250,000 for new supports, came after a single unfortunate discovery: that when the oval-cross-sectioned plasma ring was at its maximum elongation, the plasma snaked up and down and escaped control. In this shot, the plasma finally shorted out through the vacuum wall with currents of several megamps, and jolted the vacuum chamber with forces of hundreds of tons-weight. The force shook the floor like an earthquake, and although JET was not seriously damaged (it is now a millimetre longer than before) it has been thought prudent to modify its support structure.

Otherwise, JET has been running well, and made one particularly tantalizing discovery in the last two weeks of its recent closedown (to introduce neutral beam heating). The team has found that a carbide layer a few molecules thick can be deposited on the inconel inner surface of the vacuum chamber by making a glow discharge in a mixture of methane and hydrogen gas, and that this layer dramatically reduces the amounts of metal impurities entering the chamber from the wall. As these high atomic-number impurities efficiently radiate heat from the plasma, it is important to control their number.

Until this work, it had appeared that impurities would be a bigger problem at JET than expected. The carbide layer may bring a striking improvement. And because the layer can be efficiently removed, controlled experiments can be attempted. The effect was also seen earlier at the TEXTOR torus at Jülich, West Germany, but not followed up. In any case, it should not be over-emphasized, says JET physicist Alan Gibson.

Meanwhile, JET staff are crossing their fingers that Europe will come up with the cash JET needs. "JET is the only really successful example of European co-operation anywhere", claims Kind, "so there is a considerable political will to keep us going." Moreover, the present Irish presidency of the European Commission has put the 1985–89 nuclear fusion programme near the top of its priorities for agreement by the end of this year.

One explanation may be that Ireland sees JET as one of the few problems it can solve. JET officials, however, note uneasily that less senior Irish representatives in Brussels who have been discussing the fusion programme have been, with Greece, among the most negative. Who means what should be clearer at the November and December meetings of the research council.

Robert Walgate

Conservation in Japan

Modest gain for UK royal

Tokyo

PRINCE Philip, Duke of Edinburgh, has wrung some modest concessions on conservation from the Government of Japan. In his capacity as president of the World Wildlife Fund (see also *Nature* 18 October, p.595), the prince was last week promised that steps would be taken to restrict the import of endangered wildlife species into Japan. But the six-day visit did not yield all the prince had asked for.

In a 20-minute meeting with the prince, Japan's Prime Minister Yasuhiro Nakasone said that he would consider the introduction of domestic legislation to prevent the illegal import of protected species. A task force to study the problem is to be set up immediately. Customs officers are also to receive training in detecting illegal imports — the lists of endangered species are long and complicated and some dealers have skilfully forged documents.

The Minister for International Trade and Industry, Hikosaburo Okonogi, also promised to introduce by next April a system that will require dealers in endangered species to produce export permits from the governments of the nations from which the species are claimed to have come.

Rather less was promised though, in dealing with the vexed question of the 14 endangered species — six species of whale, three species of turtle, three species of monitor lizard, the musk deer and the African saltwater crocodile — which Japan refused to include in a list of endangered plants and animals and their products when it first became a signatory of the Convention of International Trade in Endangered Species, the Washington Convention efforts to reduce the number of species on the list, but gave no clue as to how or when this might be done.

Interest was also shown in the prince's desire to have Japan stage a conference on the protection of nature on islands. Among the prince's stops on his six-day tour of Japan was the island of Amami Ōshima, one of a group of remote islands known as the "Galapagos of Japan" and containing many endemic species of mammal, including the Iriomoto wildcat and the Amami rabbit.

Prince Philip had also expressed, in very diplomatic terms, his reservations about Japan's plans to continue sperm whaling in coastal waters, despite the International Whaling Commission's agreement to ban all sperm whale hunting. The Japanese whaling fleet, however, left harbour last Friday to hunt for sperm whales. The Japanese Government is now waiting to see what will happen once a whale is caught — will the US Government carry out its threat to cut Japan's fishing quota in US waters? Japanese officials had earlier expressed confidence that the United States would not retaliate even if whales were caught. Talks on the issue in Washington last week, however, were inconclusive.

Quite separately, the US Department of Commerce also announced last week that it would give Japan only a quarter of the fish quota in US waters it had requested for the rest of this year because of evidence that the Japanese fishing fleet had systematically violated earlier agreements. Whether such action will be extended if sperm whales are caught will depend on the strength of the US conservation lobby.

Alun Anderson

Nobel prize

Merrifield wins in chemistry

THOSE who have followed the growth of peptide research over the past twenty years will have received with delight and no surprise the news of Bruce Merrifield's Nobel Prize for Chemistry. The simple solid phase technique for the chemical synthesis of peptides which bears his name has been adopted in scores, possibly hundreds, of research laboratories worldwide. The concept has been widely applied in other areas of research, notably in oligonucleotide synthesis, with important consequences for genetic engineering, and in structural studies including protein sequencing.

To understand the impact that Merrifield's technique has made upon the development of peptide synthesis itself, it is necessary first to sketch in the situation in the 1950s and earlier. Peptide chemistry was then in an expansive mood. Natural peptides with powerful and important biological action, such as the pituitary hormone oxytocin, were being isolated. These natural peptides were soon shown to consist of short chains of the same building blocks (the α amino acids) as constitute the proteins. The sequence of amino acids in these linear chains was soon determined and the stage was set for the understanding of biological activity in terms of these relatively simple sequences. The techniques of peptide synthesis — the chemical union of α amino acids into chains of defined sequence — had been growing steadily during this period but were slow and labour-intensive. They could barely meet the explosive demand from pharmacologists and others for synthetic natural peptides and their structural variants which could be used to correlate chemical structure and biological activity.

It was just at this time that Merrifield introduced the simplifying step in peptide synthesis which rapidly transformed the situation. Much of the labour in contemporary peptide synthesis was involved in the isolation, purification and characterization of reaction products after each chain extension. Merrifield reasoned that by attaching the first amino acid to an insoluble polymeric support, these isolation steps could be much simplified and speeded up. There were other chemical advantages which might also increase the efficiency of synthesis — a necessary concomitant since the polymeric system did not allow separation of the products of incomplete reactions. Most importantly, the process became amenable to mechanization.

Merrifield demonstrated these advantages convincingly in 1964 with a synthesis of the nonapeptide hormone bradykinin. The hormone was prepared singlehandedly in eight days, evidently in a highly pure form. By contemporary conventional methods, it could have occupied several skilled chemists for weeks or months.

The new technique of solid phase peptide synthesis was adopted with enthusiasm by biologists, sometimes beyond its immediate capabilities at this early stage in development. Organic chemists were slower to accept its advantages, some finding it in conflict with their rigorous classical training. Within the decade, the limitations and advantages were well recognized and solid phase peptide synthesis found and established a secure place alongside more conventional methods. The number of synthetic peptides prepared with its aid must now be counted in thousands.

By the mid-1970s, improved understanding of the solid phase system and numerous technical improvements allowed successful application to oligonucleotide synthesis. This was a timely development in view of the rapid strides in genetic engineering around this time. Again, synthetic DNA fragments became much more accessible using solid phase techniques. On the structure side, solid phase methods were developed for protein sequence analysis. Throughout organic chemistry, the concept of polymer-supported reagents and reactions has become commonplace. Although Merrifield confined his own activities to the peptide field in which he has continued to make massive contributions, many of these later developments must be attributed to his inspiration. The dream of automated synthesis of artificial proteins remains to be realized, but the impact of Merrifield's work is without question.

DR Carlo Rubbia, who shares this year's Nobel Prize for Physics (see p.701).

Animal welfare

Berkeley again in trouble

Washington

THE University of California at Berkeley is awaiting with more than the usual apprehension the result of an investigation by the US Department of Agriculture (USDA) into new allegations of animal welfare abuses. The reason: $41 million of state funds earmarked for a new life sciences building cannot be spent until the university is able to satisfy the state legislature that there will be no future violations of the Animal Welfare Act. The building is already well behind schedule, and a decision by USDA to prosecute would further delay construction until the case had been decided.

Last July, the university was fined $12,000 and ordered to correct long-standing deficiences in its treatment of laboratory animals at the Berkeley campus (see *Nature* 2 August, p.356). The university was still under an order to "cease and desist" from future violations when the latest allegations were made on 10 September. Complaints were made to USDA by animal welfare groups, which entered animal houses "surreptitiously" and photographed a monkey with a tumour on its face and rabbits with local infections around cranial implants. The USDA investigation started after a surprise inspection on 12 September.

The complaint about the monkey has been dropped because USDA found no evidence of lapses in veterinary care. The care given to the rabbits is now being scrutinized, and a decision on whether to prosecute is expected before the end of the month.

Both the university and the researcher involved, Dr Walter Freeman, maintain that the animals were at all times under adequate veterinary care and that there were no violations. A university spokesman, Mr Debley, said the university "had been told" that the second complaint would also be dropped.

The requirement that the university must demonstrate compliance with the Animal Welfare Act before using state funds for the new building was written into California's 1984 Budget Act. A report by the university on the steps taken to improve animal care since the court case this summer is now being reviewed by the state legislature. Ironically, the building that may now be delayed is needed partly to improve the Berkeley campus's animal facilities. On 28 September, the university postponed an appearance before the state public works board where it was to have pressed its case for the new building. The university says the decision to postpone the appearance was due to "administrative delays" that had nothing to do with the latest allegations.

Tim Beardsley

Progress at NERC

Sir — As the new chairman of the Natural Environment Research Council (NERC), and after 8 years as a council member, I was intrigued to read your article (*Nature* 11 October, p.498) on the British Geological Survey and the related leading article (p.493) advocating the disbandment of the council.

While you have correctly identified some of the problems with which the council has grappled in recent years, I am disappointed that you have not recognized more fully the progress the council has made in the context of a severe shortage of funds.

The objective of a research council is to foster high-quality science in institutes and universities. Achieving this requires, firstly, well-motivated scientists and support staff, and secondly, money to pay them and supply the necessary support services and equipment. In spite of the council's strenuous efforts to persuade the government that environmental sciences need and deserve more funds, these have not been forthcoming on the science vote. Indeed, in the areas of NERC interest, with the exception of Antarctic research, science vote money has shrunk in recent years. Equally significant is the substantial reduction of income from commissioned research sponsored by government departments.

In the face of these reductions, my council has been at pains to maintain the level of its support for university research and has attempted to find new sources of commissioned research funds with the private sector. Contrary to your editorial comments, this has been done in line with principles clearly laid down by the Treasury, is largely on a collaborative rather than a competitive basis and is leading to the successful transfer of knowledge and technology from basic research to industry.

It will not surprise you or your readers that I reject your proposed solution to NERC's present difficulties and believe it would benefit neither science nor the country. It is a solution we have already examined and dismissed because we believe there is a real need within the United Kingdom for an organization which can promote objective environmental research to provide a basis for sound industrial, economic and political policies.

In taking up the office of chairman of NERC, I intend to continue actively the programme of reorganization and structural change which is already in hand and which, I believe, will provide purposeful support for environmental science research — basic, strategic and applied — of benefit to industry and government.

I trust that you and your readers will continue to show interest in the development of NERC and be prepared to recognize achievements resulting from reorganization as it proceeds. I believe that NERC has a strong and vibrant contribution to offer the United Kingdom and the scientific community and that the environmental sciences deserves more than the emasculation you propose.

Telling all

Sir — In his article "Widespread aftereffects of nuclear war" (*Nature* 23 August, p. 621), Dr Edward Teller points out that we should not expose the general public to highly speculative theories of worldwide destruction. Instead we should tell people exactly what we know and do not know about the nuclear winter, "for only then can decisions affecting the well-being of Western societies be made on an intelligent basis". I think that the general public would be even more satisfied if the decisions could consider the well-being of all societies.

US deficit

Sir — Your leading article "Election irrelevant" (13 September, p.92) wonders about the arithmetic of funding the US federal budgetary deficit.

In the fiscal year ending 30 September, this will be $172,000 million[1], but the trade deficit this year may exceed $130,000 million[2]. The dollars expatriated on current account are therefore sufficient to cover 130/172 or 75 per cent of the budgetary shortfall if reinvested on capital account directly or indirectly in American government securities.

Miracles

Sir — Berry *et al.* (see *Nature*, 19 July, p.171) must be born-again Baconians. This conclusion can be drawn from their statement that the laws of science are generalizations of experience and therefore cannot be applied to the examination of claims for miracles. Falsificationists would define the accumulations of scientific laws in terms of hypotheses that have so far survived empirical testing.

This subtle difference in emphasis suggests that the debunking of miracles is a job for a falsificationist whereas a neo-Baconian may be permitted the luxury of faith without being faced by a dilemma. It is however interesting to note that in fact professional illusionists appear to be better investigators of miracles than scientists, if the Yuri Geller investigation can be regarded as an exemplar of a rational examination of a claim for supernatural powers.

Berry *et al.* may therefore have arrived at a correct conclusion but for the wrong reasons. Alternatively, professional magicians perhaps may be regarded as conducting scientific research in the Popperian tradition when employed in the investigation of miracles.

Enough of Homer

Sir — M. Pulbrook (*Nature* **309**, 204; 1984), focusing on a parenthetic point I made within a quote-marked hypothetical question (*Nature* **307**, 590; 1984), has produced an interesting exegesis on black versus red Homeric wine — but the contrast I had in mind was red/*white*, or yellow. Compare the classicist W.B. Stanford, Commentary on *Odyssey*, 1947, Vol. 1, p. 355, line 196, Bk. IX: Homer "never mentions white or yellow wines". And *pace* Pulbrook, I did not assume that the key question in the wine-dark sea controversy is to "account for the redness of the sea": this surely is evident from my mention of many other aspects of the topic, formulaic devices, for example.

As the distant Homeric world-view and pattern of sensibility differ significantly from ours, our thinking about Homer's epics is easily subject to various colourations. And whatever the pros and cons of translating *οινοπα ποντον* as "wine-dark sea", the English phrase itself is viable and poetically very potent: to exemplify a facet, Kazantzakis once envied the relative monosyllabicality (!) of English.

This interdisciplinary international correspondence has been piquant. *Floreat Nature . . .*

CERN's first Nobel prize

Stockholm's recognition of the importance of the discovery of the intermediate vector bosons W *and Z is nicely tempered by an appreciation of the technical ingenuity which underlies it.*

CARLO Rubbia, Italian-born discoverer of the W and Z particles that carry the weak nuclear force, and Simon van der Meer, the Dutch accelerator designer without whom, says Rubbia, "we couldn't have done it", share the 1984 Nobel Prize for Physics. But neither is sitting back. They are, instead, separately at work on the proton–antiproton collider at the European Organization for Nuclear Research (CERN) near Geneva that won them the prize.

Rubbia is at present working flat out to exploit the collider to its utmost. There are two objectives. While the approximate masses and decay properties of the W and Z particles are now known, there is much detail yet to discover — such as the particles' lifetimes. Clearly, CERN would be well-advised to wring as much as possible from the machine before Stanford's Single Pass Collider (planned to produce a million Zs a year, compared with CERN's present few dozen) comes on line towards the end of 1987. But Rubbia and his colleagues have also been stimulated by hints from his "UA1" detector on the collider that all is not quite as expected at energies beyond the W and Z particles.

"Our chance is now" he says. Rubbia is pleased at finding the Ws and Zs, but clearly feels like an explorer who arrives at the South Pole and finds footprints in the snow — here, the footprints of Abdus Salam, Steven Weinberg and Sheldon Glashow whose "electroweak" unification predicted the presence and exact properties of the particles. "For me these anomalies — and I must be frank with you, we're not sure they're there — represent hope", he said last week. "We may be on the threshold of a whole new territority."

Rubbia has been the driving force behind the collider. "The road was very long", he said. "You have to be a hell of a persistent person. You have to be very stubborn." With two American colleagues, he first presented the idea, in 1976, to Robert Wilson, then director of Fermilab near Chicago, who rejected it. Rubbia, ebullient and outspoken, feels the reasons were partly personal. "I didn't get on with Wilson. He'd had enough of me." Fermilab went ahead instead with its Tevatron project, an upgrade to 1,000 GeV beams. (This was a lengthy project, involving the development of superconducting magnets, and it will not provide competition for the CERN collider before 1986-87 — when it will collide protons and antiprotons at 2,000 GeV total energy.)

The Rubbia project went ahead instead at CERN, assisted by the better vacuum in the CERN super proton synchrotron, through which the colliding proton and antiproton beams now circulate. In the poorer Fermilab vacuum, the beams would have been rapidly damped, and a new beam-tube would have been necessary. CERN also had van der Meer ("our best accelerator man"), whose essential contribution to the collider has been "stochastic cooling", a technique which allows an accumulation of antiprotons to collide with protons in the collider.

Stochastic cooling is much more than a technical *tour de force* but, on the face of things, is a violation of Liouville's theorem of statistical mechanics describing the motion of collections of particles. Only once before has a Nobel prize been awarded to an accelerator physicist — Ernest O. Lawrence, for his design of the cyclotron. The comparison of van der Meer with Lawrence is a measure of the stature of the Dutchman's achievement.

The problem van der Meer has solved is this. Antiprotons are formed in high-energy collisions of a proton beam with a target, and collected into a rough beam. But the particles so produced have a wide spread of velocities, and so could not be accelerated coherently in a synchrotron machine. The velocity spread has to be reduced or, in the jargon, the beam has to be "cooled". An earlier (1960s) Soviet solution (due to the late Gersh Budker of Novosibirsk) was to inject a "cool" (mono-energetic) beam of electrons to run alongside the protons: the electrons would "heat up" and the protons "cool" until the beams reached the same "temperature" (this thermodynamic analogy is exact). Then further cooling would be done with a new injection of electrons until the proton beam was sufficiently cool that it could be accelerated up to the 270 GeV planned in the collider (the super proton synchrotron). This idea worked, but proved too complicated to use in practice.

van der Meer's approach is different. Liouville's theorem has it that the crowd of points representing a collection of particles in phase space (embodying both momentum and position) will keep a constant density, whatever the external forces acting on it. According to Liouville, a beam is like toothpaste in a tube: if you squeeze it somewhere in phase-space, it must come out somewhere else. But "cooling" aims to increase phase-space density, by putting all the particles in a physic bunch in real space, each with the same momentum. How does van der Meer's cooling method get around this difficulty?

"I began thinking that if you can control a single particle perfectly in an accelerator, then why can't you control several?" he says. He developed the idea that an uncooled beam of particles is represented in phase space by points (one for each particle) with plenty of space between them, and that in principle these points can be squeezed closer to each other without changing the phase-space density around each point.

In practice, the technique is to control the fluctuations of the beam. Antiprotons are accumulated in a storage ring called the Antiproton Accumulator. Sensors detect deviations at one point on the ring, ultra-fast electronics calculate the necessary corrections and correcting signals are relayed to some point later in the trajectory. The process is possible — with both beam and signal travelling near the speed of light — because a chord of a circle is shorter than the circumference which it intercepts. This whole correction process takes a few tens of nanoseconds, and is repeated for each circuit of the beam. Roughly 24 hours are needed to accumulate and cool enough antiprotons for a collider run, but van der Meer is working on a new accumulator (ACOL) that will reduce this by a factor of ten.

ACOL will take its first beam only in May 1987. Meanwhile, Rubbia and his 130-strong UA1 collaboration* will try to get as much time and energy as possible to explore the "new territory".

Robert Walgate

***The UA1 group includes teams from West Germany (Aachen and Kiel), Austria (Vienna), CERN, the United States (Harvard, Riverside and Wisconsin), Finland (Helsinki), Italy (Padua and Rome), France (Annecy, Collège de France and Saclay), the Netherlands (Amsterdam) and the United Kingdom (Birmingham, Queen Mary College London and the Rutherford-Appleton Laboratory).**

Erratum

IN the penultimate paragraph of Stephen Budiansky's article "Jumping the smoking gun" (*Nature* 4 October, p.407), the statement that "none of the bacteria residing in the gut of farm animals is resistant" should have read "not all of the bacteria . . .".

Photoreception

Bovine-like rhodopsin in algae

from Howard C. Berg

THE outer segment of the light-sensitive retinal rod has long been the system of choice for work on phototransduction in vision, from the isomerization of 11-*cis* retinal to the transient closure of sodium channels in the plasma membrane. Recent advances have centred on amplification involving GTP–GDP exchange, on activation of phosphodiesterase and on hydrolysis of cyclic GMP (Stryer, L. *Cold Spring Harb. Symp. quant. Biol.* **48**, 841; 1983). To those of us who work on sensory transduction in microorganisms, for example on chemotaxis in bacteria, it seems remarkable that so much has been learned without the use of genetics. There is nothing like the right mutant to open the door to fresh discovery, to reveal an unsuspected component or process essential to the function of a complex biological machine. The report on page 756 of this issue that the green alga *Chlamydomonas* can see with the aid of a bovine-like rhodopsin foreshadows a renaissance in studies of eukaryotic photoreception.

Chlamydomonas is an aquatic organism about 10 μm in diameter that is propelled along a helical path by means of two anterior flagella. For photosynthesis, the cell uses blue and red light, which it detects using one chloroplast while for phototaxis, it uses blue-green light, which it detects with one lateral eye, or eyespot. It swims towards or away from a source of light, aligning the axis of its helical path with that of the beam. In 1980, Foster and Smyth argued that the eyespot is a directional antenna, comprising alternate layers of material of different refractive index, that enhances contrast on a layer of photoreceptor pigment in the overlying plasma membrane (*Microbiol. Rev.* **44**, 572). They noted that this antenna completes a 360° lateral scan of the environment every time the cell advances one helical turn. Using a phase-sensitive system that causes one flagellum to pull harder than the other when the output of this scan is non-uniform, the cell can correct its course and 'lock on to' the beam. On the basis of the phototactic action spectrum and other optical properties of the cell, they predicted that the photopigment would be a bovine-like rhodopsin.

Now Foster and his associates, using retinal analogues provided by Nakanishi's group, have proved the point. Phototaxis of a carotenoid-free mutant is restored on addition of suitable analogues, and the shifts in the action spectra parallel those seen in absorption spectra of bovine rhodopsins. The pigment protein clearly differs from bacteriorhodopsin, which works with different analogues and has different spectral properties.

Most steps of the sensory pathway remain to be worked out. Coupling to the flagella presumably occurs via changes in membrane potential, since such changes are observed, with the appropriate action spectrum, when a related green alga, *Haematococcus*, is exposed to light (Litvin, F.F., Sineshchekov, O.A. & Sineshchekov, V.A. *Nature* **271**, 476; 1978). The two flagella of *Chlamydomonas* have different sensitivities to calcium ions (Kamiya, R. & Witman, G. B. *J. Cell Biol.* **98**, 97; 1984), so voltage-sensitive calcium channels might be involved. Little is known about how light absorption generates changes in membrane potential. It is at the level of these early steps in phototransduction that we can expect to see the most significant advances.

Lest anyone should doubt the power of genetic and biochemical dissection in *Chlamydomonas*, look how it has broadened our understanding of the assembly, structure and function of the eukaryotic flagellum (Luck, D.J.L. *J. Cell Biol.* **98**, 789; 1984). Similar breakthroughs should now be possible in studies of eukaryotic photoreception. ☐

Palynology

Andean guide to Pliocene–Quaternary climate

from J.R. Flenley

THE city of Bogota, 2,600 m up in the Colombian Andes, enjoys a remarkably level site, being built on the dry bed of a former lake. A resistivity survey has recently shown that the lake deposits are 800 m deep and have probably been accumulating continuously from well back in the Pliocene and throughout the Quaternary. This has provided a unique opportunity to obtain a complete land-based record of the climatic oscillations of the Quaternary to complement the existing deep-sea record. The results are contained in *Vegetational and Climatic History of the High Plain of Bogota, Colombia: a Continuous Record of the Last 3.5 Million Years* (Cramer, Liechtenstein; 1984), by H. Hooghiemstra.

The deep-sea record has been investigated by Nick Shackleton from Cambridge, and Neil Opdyke at Lamont-Doherty Geological Observatory. By oxygen isotope analysis of the shells of foraminifera from the ocean-bed ooze they have shown that there were numerous major climatic cycles in the past 1.6 Myr, that is since the Olduvai magnetic event which provides one possible definition of the Pliocene–Quaternary boundary. Oxygen isotopes, however, though giving an indication of the amount of ice in the world and of the palaeotemperature of the ocean surface, tell one little about ecological conditions on the continents. In that respect the continuous land-based record from Bogota is very important indeed.

The Bogota sediments have now been cored to a depth of 357 m. Fortunately they contain numerous bands of volcanic ash, which can be dated by the potassium–argon method, allowing it to be established that this part of the record covers the last 3.5 Myr. The monumental task of pollen-analysing this core fell to Henry Hooghiemstra and O.K. Hulshof, working with Tom van der Hammen at the Hugo de Vries Laboratorium in Amsterdam. After 1,230 pollen samples and 378 pollen and spore types, they graphed their results with a laser-beam plotter.

The resulting diagram has been divided into no less than 55 zones, representing 27 complete major climatic cycles, which can be correlated with those from the deep-sea record, and extend it much further back in time. The fluctuations in mean annual temperature are from <6°C to >15°C — so much for those who would write off Quaternary temperature change in the tropics. Some of the most marked fluctuations and some of the coolest temperatures occur in the Pliocene part of the record. It seems that the Late Tertiary was not the time of gently declining temperatures which it was once thought to be.

The great advantage of a land-based core over an ocean core is that it gives direct biogeographical and ecological information. The Isthmus of Panama and the Andes were formed relatively late in the Tertiary, before which it was almost impossible for taxa from North America to migrate into South America. In the Bogota record, we can actually see the arrival of the North American trees *Quercus* and *Alnus*. *Alnus* arrived in the Late Pliocene, about 2.9 Myr ago; *Quercus* appeared on the scene only 1.0 Myr ago. Such direct evidence of migration provides a factual basis for biogeography and offers essential tests for the hypotheses put forward by students of modern biogeographical distributions.

The major ecological cycle recorded is the alternation of rain forest elements with those from the paramo, the grass-dominated vegetation above the tree line. It is these alternations which provide the evidence for temperature fluctuation. Careful inspection of the pollen curves shows that no two cycles are precisely the same. *Alnus*, after its arrival, usually dominates the forest pollen, but the proportions of other forest trees such as *Podocarpus, Weinmannia, Hedyosmum, Rapanea* and *Miconia* vary rather widely and are constantly fluctuating. Some of these variations may indicate hydrological differences between the forest periods, but others could relate to the population biology of individual taxa or to complex ecological interactions. Two points emerge: there is no set pattern of succession in each forest period and there is no stable 'climax'. In fact the diagram is more an exhibition of continuous change than of any kind of stability; any idea of the rain forest as a stable museum-piece does not apply to these montane forests.

Is the Bogota record unique or can we hope to find similarly long undisturbed records elsewhere? In glaciated parts of the world it is clearly unlikely and in subtropical arid regions deposition may often have been interrupted by aridity and by deflation of sediments. It is therefore no accident that this valuable record is from the tropics. The Bogota lake happens to be dry, but there are other tropical lakes which are wet and almost certainly contain long records. The most likely examples are the East African Rift Valley lakes, although the tectonic lakes of the Sumatran Rift Valley also hold out much promise. What is needed now is an international coring project for tropical deep lakes. A start has been made by Dan Livingstone of Duke University, who plans to core the meteorite crater of Lake Bosumtwi in Ghana, and it would be tragic if the expertise to be gained so expensively in money and time at Bosumtwi were not to be more widely used.

The amount of laboratory work involved in analysing the Bogota core was enormous but that being generated by analysis of a 1,000 m core from Lake Biwa in Japan is positively daunting. How incongruous that the pollen analysis of cores obtained with such sophisticated technology is carried out with 'steam-age' manual preparation and optical microscopy. This is true not only for pure research, but also in the field of oil search where palynology is increasingly important. It seems odd that so few palynology laboratories put any effort into modernizing their techniques, and that research-funding bodies have not yet supported attempts to apply information technology in this challenging and commercially significant area. □

Evolution

Creationism in confusion

from Michael E. Howgate and Alan J. Lewis

THIS Saturday (27 October, 2.30pm, Conway Hall, Red Lion Square, London WC1) there is to be a debate between the Association for the Protection of Evolution (APE) and the Biblical Creation Society (BCS) whose talents were on display at an open day during the society's biennial conference*.

Evidently, BCS members range from 'young earthers' who are strict literalists and believe that the Earth was created in six days about 6,000 years ago, to 'mature earthers', who believe it was created about 6,000 years ago but looking much older. It even includes some who put forward the 'gap' theory, which proposes that geology happened sometime between the Fall of Adam and the Flood.

The open day was introduced by David Tyler, who set the tone by being very noncommittal about whether Hutton's classic unconformity at Siccar Point was due to the Flood. However, he was convinced that the presence of a basal breccia and a smoothly planed-off contact was due to some unnamed catastrophic event. Tyler is unusual for a creationist in that he does go into the field to look at the evidence, although he freely admits that his observations are interpreted in the light of 'the biblical constraints on (his) geological thinking'. Tyler, a young-earth theorist (and an organizer of the Open University Geology Club), disparages Uniformitarian geologists for relying on present-day observable analogies when interpreting past processes, but seems not to be averse to doing the same when using the Mount St Helens eruption as a convenient catastrophist analogy. As he is faced with a multiplicity of non-correlatable unconformities throughout the geological column, Tyler seems destined to arrive at the position of Baron Cuvier who, nearly two centuries ago, saw the necessity to interpose as many catastrophes as required in order to match up his catastrophism with the record of the rocks.

A surprising fillip for evolutionists was the discovery that BCS's top geneticist, Chris Darnbrough (Glasgow University) believes in evolution. However, his lecture *Genes, created but evolving* gave the game away. Far from his belief in the genetic mechanisms of evolution affecting his literalist faith in creation, Darnbrough believes that the 'Biblical kinds' of organisms have evolved, but only since the Flood.

In his keynote theological policy statement, Edgar Andrews, professor of materials at Queen Mary College, London, wisely distanced the BCS from US creationism, which he described as being ascriptural and anti-scriptural, as well as suffering from inconsistency. Andrews condemned the opportunist tactics of 'scientific creationism' for leaving the revealed word of God — the Bible — out of their arguments. More specifically, Andrews did not criticize the pseudoscience of the American creationists but concentrated his attack on their failure to appreciate fully the role of Christ Himself as the agency of Creation.

David Gower, reader in biochemistry at University College, London, gave a biblically uninterpreted account of recent advances in the study of olfaction. But in the finale to his lecture he opined that nasal biochemistry was firm evidence for creative design as opposed to natural selection. When tackled on the subject of inherent and genetic defects in olfaction and gustation as well as the lustful temptations presented by pheromones, Gower unenthusiastically admitted that his theological position impelled him to ascribe these faults to the Fall of Adam or to the agency of the Devil.

When a stalwart of the rival creationist organization, the Creation Science Movement, attacked the backsliding into theism of the BCS and asked for a show of hands in support of young-earth, six day, literalism, only one member of the panel of lecturers committed herself to this position. (Perhaps the presence of your Neodarwinist correspondents had an inhibiting effect on their forthrightness). It is to be hoped that at Saturday's debate with APE, the BCS protagonists will not hide the flame of their empirical predictions behind a bushel of theological diversions.

Michael E. Howgate of the Department of Zoology, University College London, WC1E 6BT and Alan J. Lewis of the Department of Electrical and Electronic Engineering, Brunel University, Uxbridge UB8 3PH, are founder members of APE.

Anthropology

Supertramps at sea

4630

from Jared M. Diamond and William F. Keegan

WHEN European navigators began 'discovering' the rest of the globe in the fifteenth century, they were surprised to find that technologically less advanced peoples had already settled many oceanic islands. The pattern of settlement is intriguing: in the tropical Pacific almost every habitable scrap of land, no matter how small or remote, was occupied, whereas in other oceans much larger and less remote islands, for example the Madeiras, Azores, Mauritius and Flinders, remained vacant. Recent archaeological work has shown that Pacific peoples colonized earlier, farther and at a lower level of overall technology than did Europeans, Africans and Amerindians. It is now possible to explain why this pattern should be so, and to draw interesting parallels between island colonization by man and that by birds and other animals.

While most Atlantic islands remained empty until thousands of years after the rise of Western civilization, stone-age hunter-gatherers reached the eastern Indonesian islands of Flores and Timor by 100,000 yr BP (ref.1), Australia and New Guinea by 50,000 yr BP (ref.1), the Bismarck Archipelago by 11,000 BP (ref.2) and the West Indies around 5,000 yr BP (refs.3,4). Madagascar was colonized by people from remote Indonesia rather than from nearby Africa, while the colonists of Hawaii and Easter Island stemmed ultimately from the west rather than from the closer Americas. The explanation for this unexpected pattern of settlement, put simply, is that the Pacific is endowed with far more islands than are other oceans.

One reason why both the area and distribution of islands are important factors for colonization is that close islands serve as stepping-stones to more remote islands. For instance, Polynesians or Caribbean Indians did not reach Easter Island or Cuba in a single leap from New Guinea or Venezuela, but via many intermediate islands. But stepping stones cannot be the whole explanation. To reach remote Pacific islands such as Easter Island, New Zealand and Hawaii, Polynesians had to cross stretches of open ocean of up to 3,500 km (refs 5,6), far greater than the distances from the nearest mainland to the Atlantic and Indian Ocean islands that Africans and Europeans failed to reach until modern times. This suggests that the availability and initial discovery of many habitable Pacific islands stimulated overwater colonization by humans. For similar reasons the bird species of New Guinea include many more superior overwater colonists than do the birds of South America or Africa. Thus, understanding of island colonization by humans[7,8] raises problems similar to the island biogeographical problems that have long fascinated students of plant and animal distributions[9].

For European navigators the effect of island availability on colonizing effort is obvious. Between 1400 and 1800 the discovery and expectation of habitable land catalysed further voyages dedicated to exploration and settlement. Egocentric Europeans have tended to assume, however, that only they explored consciously, while illiterate stone-age peoples must have reached islands by accidental drift voyages[10]. Archaeologists still believe this theory holds for the settlement of Australia and New Guinea from Indonesia. The first securely dated human remains from Australia/New Guinea (united to each other in the Pleistocene) date from around 50,000 yr BP (ref. 1), and there is no proof of a second wave of human colonization until the arrival of pigs, taro and dogs of Asian origin around 5,000–10,000 yr BP. In this case, the simplest interpretation is that one raft-load from Timor or the Moluccas survived after being swept to Australia/New Guinea[11], and that a similar accident did not happen again for 40,000 yr.

Portrait of a New Zealand man by F. Parkinson, on Cook's first voyage, 1768-71 (British Library).

By contrast, for the Mediterranean and Polynesia, archaeological research has shown that colonization could only have been purposeful. The presence of obsidian from the Aegean island of Melos on the Greek mainland demonstrates overwater voyaging in the eastern Mediterranean around 13,000 yr BP (ref.12). Yet mainlanders did not choose to begin settling eastern Mediterranean islands until the rise of agriculture and domestication first made self-sustaining human populations possible on the largest islands around 8,000 yr BP. Settlement gradually spread to smaller Mediterranean islands as subsistence techniques improved over the following five millenia[12].

In Polynesia, not only settlement but also discovery of many islands must have resulted from purposeful voyaging. Computer simulations and historical records show that there is essentially no chance of eastern Polynesia having been reached by accidental drift voyages[13,14]. Detailed studies of Polynesian navigational techniques[15], and the Hawaii-to-Tahiti sea trial of the reconstructed Polynesian canoe Hokule'a[16], have demonstrated that the exploration of the Pacific was within Polynesian voyaging capabilities. Polynesian islands were discovered during a series of upwind voyages that reached Fiji, Samoa and Tonga slightly before 1000 BC, the Marquesas around AD 300, and all other Polynesian islands over the following 500 yr (refs 5,6). Human introductions of crops and domestic animals throughout Polynesia provide abundant evidence that settlement as well as discovery was planned[17].

All this is not to say that prehistoric navigational skills were such as to ensure risk-free exploration and colonization. On the contrary, the settlement of Polynesia is estimated to have cost 500,000 Polynesian lives at sea, a number equal to Polynesia's standing population once settled[5]. The motivation of prehistoric voyagers was strong, however. Those few fifteenth and sixteenth century European navigators who returned alive told tales of wealth and habitable lands that triggered an explosive exodus of Europeans seeking these and other still-undiscovered lands. Similar reports of discovering empty islands must have driven the explosive wave of colonization in Polynesia between AD 300 and 800. With the occupation of all the Pacific's habitable islands, the main motivation for long-distance voyaging ceased, and it was only a memory by the time Europeans reached Polynesia.

The patterns of distribution of Polynesians in the eastern and western Pacific contrast dramatically[5]. On archipelagos lacking other peoples (from Tonga eastwards, including New Zealand), the Polynesians occupied all islands. On tropical western Pacific archipelagos from the New Hebrides to the Carolines, which are shared with Melanesians and Micronesians, the Polynesians occupied only small or outlying islands. In the Solomons, for instance, Polynesians were confined to Rennell and six other outliers, while Melanesians were on all other islands. How could Polynesians have swept thousands of miles across the Pacific from eastern Polynesia to New Zealand and Rennell, without completing the last jumps of 1,000 and 100 miles respectively to Australia and the central Solomons?

The answer proves to be that Polynesians were excluded by established human populations on Australia and western islands other than small outliers: the Rennellese who reached the central Solomons are known to have been killed and eaten. For Australia, a similar exclusion is inferred from Polynesian-style stone axes found along the east coast. The distribution of Polynesians on Pacific islands is paralleled in detail by distribution of numerous bird, bat, lizard, snail and plant species (termed supertramps), which are similarly confined to outlying islands in western archipelagos by established related species[18]. Other cases of human supertramps excluded from mainlands are the Norse from Newfoundland by Amerindians[19] and West Indian Arawaks from Florida by other Amerindians. ☐

Astronomy

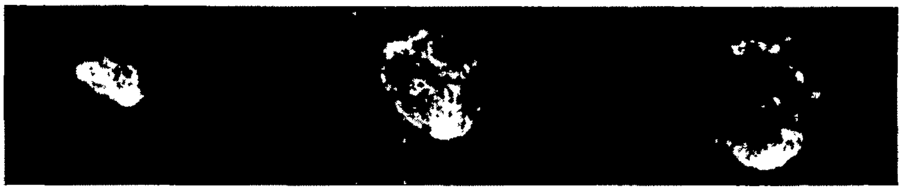
Chaotic spinning of Hyperion?

From Carl D. Murray

FOR many people the Solar System is a paradigm of ordered regular motion. Indeed, the origins of mechanics can be traced to the early attempts to explain the observed regularity in the motions of planets and satellites. However, according to recently published work by Jack Wisdom and Stanton Peale of the University of California, Santa Barbara, and François Mignard of CERGA, Grasse, the Solar System probably contains one permanent member, Saturn's satellite Hyperion, whose rotational behaviour is far from regular (*Icarus* **58**, 137; 1984).

A general feature of chaotic motion is that relatively simple equations can give rise to solutions with complicated unpredictable behaviour, the degree of chaos depending on a number of factors. The common analogy of a deterministic yet chaotic system is a pinball machine, where small changes in starting conditions can produce radically different results. Hyperion's orbital motion and its interaction with the satellite Titan are quite well understood, and apparently regular. What Wisdom, Peale and Mignard have investigated is the effect of Hyperion's unusual shape on its spin behaviour.

Most of the natural satellites in the Solar System exhibit what is known as synchronous spin-orbit resonance, that is, the satellite's spin period is approximately equal to its orbital period. The most familiar example of this configuation is the Earth–Moon system, resulting in the Moon always presenting the same face to the Earth. Such configurations are not due to chance but have arisen because of the effects of tides raised on the planet by the satellite, the time scale for the process depending on the mass of the satellite and its distance from the planet. For Hyperion, which is small, this time scale was known to be a significant fraction of the age of the Solar System, even before the Voyager missions, but observations had not produced a definitive spin period. In 1980 and 1981 Voyager images of Hyperion revealed a satellite with a highly irregular shape which has been variously described as resembling a cigar or hamburger (see the figure). Wisdom *et al.* show that it is this unusual shape which will probably prevent Hyperion from ever achieving a stable spin-orbit configuration.



Three images of the saturnian satellite Hyperion from Voyager 2 spacecraft. (JPL and NASA.)

A spin-orbit resonance can occur when the ratio of the spin period to the orbital period is some simple fraction. Near-spherical objects can be trapped in a number of different spin-orbit resonances other than the synchronous one — the planet Mercury is actually in a 3/2 spin-orbit resonance. Each resonance occupies a well-defined region in the phase space and has a narrow chaotic region at its boundary. Only in this narrow region does the behaviour of the spin become unpredictable. If the satellite shape is irregular, with large differences in the principal moments of inertia, then nearby resonances start to overlap and the extent of the chaotic region dramatically increases. A criterion for the onset of chaos as a result of overlapping resonances was first developed by Chirikov (*Phys. Rep.* **52**, 263; 1979) in connection with work on plasma confinement. With parameters appropriate for Hyperion, Wisdom *et al.* show that the chaotic region around the synchronous state is so large that the 3/2 state vanishes and the 1/2 and 2 states are reduced to small islands of apparent stability in a sea of chaos. If Hyperion finds itself in this large chaotic region, its spin period will undergo essentially random variations over a few orbital periods. Nevertheless, Hyperion could still survive in the synchronous state provided that its spin axis remained perpendicular to the orbital plane. But Wisdom *et al.* have also carried out an attitude stability analysis and shown that the synchronous and 1/2 states are unstable to small displacements, resulting in a chaotic tumbling motion. Hyperion's only hope for a chaos-free existence is to enter the attitude stable 2 state. The probability of such an event is very low, however, so Wisdom *et al.* conclude that Hyperion will be found to tumble chaotically.

This naturally leads to the question of what evidence is available in the Voyager images to support a claim for the chaotic tumbling of Hyperion. Thomas *et al.* estimate a rotational period of 13 days (*Nature* **307**, 716; 1984), which, since the orbital period is 21 days, tends to confirm that Hyperion has yet to reach synchronous rotation. They also claim, however, that Voyager 2 images show a spin which is coherent over 61 days and that the derived spin period is consistent between the Voyager 1 and Voyager 2 photographs, even though the sequences were made 220 days apart. If Hyperion has maintained the same spin period for this length of time then the balance swings in favour of ordered rather than chaotic motion. Wisdom *et al.* argue, however, that if the spin is chaotic, with variations over a few orbital periods, then the standard technique of fitting observations made at different times to a constant period is not applicable. The conflicting evidence can only be resolved by an accurate determination of Hyperion's light curve.

Wisdom *et al.* give a convincing demonstration of how some of the techniques of modern dynamics can be applied to the Solar System. It remains to be seen whether or not the 'majestic clockwork' of Kepler and Newton has an unpredictable component.

Plant engineering

More prospects for Ti plasmids

from M.H. Drummond

AGROBACTERIUM TUMEFACIENS causes crown gall tumours in some gymnosperms and most dicotyledonous angiosperms[1] by inserting its Ti plasmids into the nuclear genome of the infected plant; and agrobacterial Ti plasmids are now well established as vectors for introducing foreign genetic material into a wide range of higher plants[2,3]. This may ultimately make possible useful additions to the genomes of crop plants. Unfortunately the prospect for using Ti-based vectors in monocotyledonous plants has been gloomy because *A. tumefaciens* is not a pathogen for them, a matter of considerable regret since the monocots include the grass crops, which feed the greater part of mankind. On page 763 of this issue, however, Hooykaas-Van Slogteren *et al.* indicate that Ti plasmid DNA enters the cells of at least some monocot species, but is simply not oncogenic[4]. Vectors based on Ti plasmids may thus be useful in monocots after all.

The observation made by the Dutch group concerns the presence in plant tissue of opines. These metabolites are absent from normal tissue but are synthesised in large amounts in crown gall tissue by synthases encoded in T-DNA, the Ti plasmid segment that is integrated into the plant genome. The best known opines, octopine and nopaline, characterize the two principal varieties of Ti plasmid. Ti plasmid sequences outside the T-DNA segment encode oxidases that catabolize opines in the bacterium. Thus the plasmid both diverts the biosynthetic resources of the plant and enables its bacterial carrier to exploit the resulting opine pool as a very specific carbon and nitrogen source. This strategem has been termed genetic colonization. The ecological niche it creates is further enlarged by multiplication of opine-producing cells into a crown gall tumour. This is brought about by other T-DNA genes which perturb hormone metabolism in the plant cell, raising the level of both auxins and cytokinins[5]. The Ti plasmid vectors developed for genetic engineering can be 'disarmed' by deleting, or otherwise mutating, their oncogenic genes, in order to permit differentiation of engineered tissue into entire plants[3,6].

The Dutch group find that when certain ornamental monocots are infected with virulent strains of *A. tumefaciens,* opine synthesis ensues in the absence of any sustained neoplastic growth. Opine synthase genes are known to be under the control of eukaryotic regulatory sequences[7]. The remote possibility that they are being expressed by the bacterial cell in this system is excluded by the observation that no octopine synthesis is detectble when T-DNA transfer is blocked by a plasmid mutation, *virB*, outside the T-DNA[8]. The obvious interpretation is that T-DNA does enter the monocot cell, but fails to bring about oncogenesis. If so, Ti plasmids, far from being unsuitable for the genetic engineering of monocots, can be considered well-suited because already disarmed, although it remains to be seen whether the Dutch group's observations can be extended to the important grass crops.

The definitive experiment, demonstrating the presence of T-DNA sequences in monocot tissues by nucleic acid hybridization, remains to be carried out. Southern blotting is now used routinely to characterize DNA sequences inserted into dicot genomes[2,3,9], but this is more problematical for monocots because of difficulties in the culture of large amounts of transformed tissue without significant contamination by normal cells. In dicots the hormone autotrophy conferred by T-DNA facilitates the selection and growth of transformed tissue, and in many species the establishment of tissue culture lines from single cells is quite straightforward. This is not yet the case for monocots but other means of deriving monocot tissue enriched for cells containing inserted DNA should be feasible. For example, a Ti vector encoding neomycin phosphotransferase such as that constructed by Bevan *et al.*[9] could be used in combination with G418 drug selection in tissue culture. Neomycin resistance is expressed from the *nos* (nopaline synthase) promoter in this construct, which underlines the importance for monocot genetic engineering of the present demonstration that synthase genes are transcribed in the monocot genetic background.

If T-DNA is integrated into the monocot genome in its entirety, its failure to induce tumorigenesis must be accounted for. There are two obvious possibilities: either the oncogenic genes are not properly expressed, or their protein products fail to disrupt control of cell division. If the oncogenic genes are not transcribed, then comparing their regulatory regions with the *nos* or *ocs* (octopine synthase) promoters might bring to light differences between monocot and dicot promoter sequences. However, the Dutch group seem to favour the second possibility.

The work has one further interesting aspect. By illustrating nicely that oncogenesis is not an essential part of genetic colonization, it raises the question of whether other procaryotes have evolved similar stratagems for exploiting plant or animal hosts. To discover any that were a tenth as useful as Ti plasmids would be very exciting, but in the absence of any obvious pathogenic effect, how does one start looking? □

DNA recombination

Resolution of intermediates

from Nancy L. Craig

HOLLIDAY structures[1] are thought to join DNA duplexes by a reciprocal single-strand exchange and are thought to be intermediates in various pathways of genetic recombination (Fig. 1). They have been visualized by electron miscroscopy, but biochemical evidence in support of their role in recombination has been hard to come by. Now, proteins encoded by *Escherichia coli* phages are beginning to provide information about breakage and rejoining reactions that can mediate the formation and resolution of Holiday structures. Kemper *et al.*[2] and de Massy *et al.*[3] have characterized phage endonucleases that can specifically cleave Holliday structures *in vitro*, probably reflecting an important step in the resolution of Holliday intermediates in homologous recombination. And on page 721 of this issue, Hsu and Landy show that Holliday structures can be resolved *in vitro* to recombinant duplexes by the site-specific recombination machinery of phage lambda, providing strong evidence that Holliday structures are intermediates in this recombination pathway[4].

Integration of phage lambda into the *E. coli* chromosome occurs by reciprocal combination between *att*P(POP′), a ~240-base pair (bp) specific site in the phage chromosome, and *att*B(BOB′), a ~25-bp site in the bacterial chromosome[5] (see Fig. 2). The products of integrative recombination are the hybrid sites *att*L(BOP′) and *att*R(POB′) which flank the integrated prophage. Prophage excision occurs by reciprocal recombination between *att*L and *att*R, regenerating *att*P and *att*B. Each *att* site contains the same

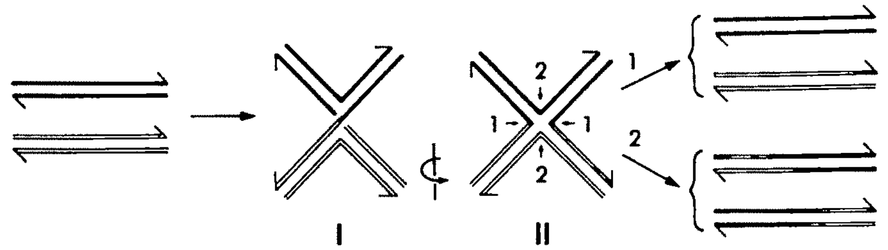

Fig. 1 Formation and resolution of a Holliday structure. The polarity of the strands in two DNA duplexes is indicated by the arrowheads. A Holliday structure (I) is formed by breakage, exchange and rejoining of a pair of strands of like polarity at equivalent positions. Rotation produces II, an isomer of I. A Holliday structure is resolved by breakage, exchange and rejoining of a pair of strands of like polarity at the branch point; the outcome depends on whether this occurs at positions 1 or 2.

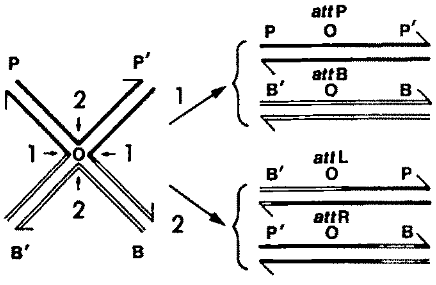

Fig. 2 Resolution of a Holliday intermediate in lambda site-specific recombination. A Holliday structure containing *att* sites is shown. P, P',B' and B are the main *att* sites. The branch point occurs in the core (O), a sequence common to all *att* sites. Resolution at positions 1 yields the products of excisive recombination, *att*P(POP') and *att*B(BOB'). Resolution at positions 2 yields the products of integrative recombination, *att*L(BOP') and *att*R(POB').

15-bp core (O), flanked by unique arms (P, P', B, B'); see Fig. 2. Integrative recombination requires Int, a lambda-encoded protein, and integration host factor (IHF), a host-encoded protein. Excisive recombination requires Int, IHF and Xis, another phage-encoded protein. These proteins are specific DNA-binding proteins and the *att* sites contain elaborate arrays of recognition sequences.

Using a method developed by Bell and Byers[6], Hsu and Landy[4] constructed pairs of *att* site-containing DNA duplexes with four non-homologous arms (Fig. 2) joined by a reciprocal single-strand exchange in the core. Incubation of these structures with purified Int resulted in their resolution to the products of excisive and integrative recombination. Both pairs of recombinants are observed because resolution can occur either at positions 1 or positions 2 of the Holliday structure (Fig. 2). These experiments suggest that natural Int-dependent recombination proceeds via the formation of a Holliday structure by a reciprocal single-strand exchange between the cores of *att* sites, followed by its resolution by a second reciprocal exchange.

The demonstration that Int alone can promote resolution emphasizes its central role in strand exchange and extends the finding that Int has specific topoisomerase activity which breaks and rejoins DNA at the junction-type Int recognition sequences in the cores of *att* sites[7]. Hsu and Landy show that resolution, like recombination, proceeds in the absence of a high energy cofactor and produces intact duplexes, features reflecting the action of a topoisomerase. Moreover, they also found that Int's capacity for resolution is specific to Holliday structures containing *att* site cores at the branch point. Int can resolve synthetic Holliday structures that lack distal segments of the arms of the *att* sites but does not resolve synthetic Holliday structures which lack the core. Thus, it is likely that Int topoisomerase mediates strand exchange by promoting sequence-specific breakage and rejoining reactions in the cores of *att* sites and that these reactions form and resolve Holliday structures. The action of topoisomerases may also underlie other site-specific recombination reactions[8,9].

What are the roles of the other components of the lambda site-specific recombination machinery? Hsu and Landy show that sequences in the *att* site arms which are essential for recombination are not required for resolution. This suggests that the interactions of IHB, Xis and Int with their recognition sequences in the arms of *att* sites are important in promoting the formation of a Holliday structure. The formation of such an intermediate is a multistep reaction in which recognition of the *att* sites by the recombination proteins and synapsis of the *att* sires precede the strand-exchange step, which is mediated by the interaction of Int with the core. The assembly of the *att* sites and recombination proteins into organized complexes[10] may facilitate these steps.

Hsu and Landy have also observed that, although an *att* site-containing a Holliday structure can be resolved by Int alone to the products of either integrative or excisive recombination, the relative efficiencies of these two reactions vary under different experimental conditions. This suggests that resolution may also be regulated by other components of the recombination machinery.

Formation and resolution of Holliday structures is also probably involved in strand exchange in homologous recombination. Study of the *E. coli recA* protein is revealing how Holliday structures can be formed during homologous recombination[11]. How can they be resolved? Purified endonuclease VII (endo VII), an enzyme encoded or regulated by coliphage T4 gene 49, cleaves Holliday structures *in vitro* by breaking pairs of DNA strands of like polarity at the branch point — that is, at positions 1 or positions 2 (see ref. 12). De Massy *et al.*[3] have now shown that phage T7 endonuclease I, which is the gene 3 product, has similar activity. It has now been shown that endo VII (refs 2 and 13) and endo I (ref. 3) cleave at the branch points of cruciforms which occur at short inverted repeats in supercoiled DNA. This result suggests that such cruciforms are useful analogues of Holliday structures and that these enzymes will also be useful as probes of cruciform structure.

The resolution of Holliday structures promoted by endo VII and endo I is significantly different from Int-promoted resolution. In contrast to Int, whose resolving capacity is limited to *att* site-containing Holliday structures, endo VII and endo I are capable of resolving Holliday structures that contain a variety of sequences, although endo VII has a modest sequence preference[2]. Furthermore, in contrast to Int, neither endonuclease promotes rejoining of the DNA strands they break. Thus, in homologous recombinations of bacteriophage DNA, resolution of Holliday intermediates to intact recombinant duplexes probably involves the action of other enzymes, for example, DNA ligase. It is also likely that endo VII and endo I participate only in the resolution step in recombination, whereas Int mediates both the formation and resolution of recombination intermediates.

Hsu and Landy provide the first physical evidence that Holliday structures are intermediates in phage lambda site-specific recombination. It will now be possible to dissect separately the formation and resolution of these intermediates. Although further work is needed to establish that endo VII and endo I participate directly in homologous recombination between phage DNA molecules *in vivo*, detection of activities that can resolve Holliday structures supports the hypothesis that these structures are recombination intermediates. Using the methods developed to detect the activity of endo VII and endo I towards Holliday structures, it should be possible to search for similar cellular activities.

Meteorology

Origins of stony-iron meteorites

from Edward R.D. Scott

ALTHOUGH most of the meteorites that fall on Earth are chondrites, more is known about the formation and parent bodies of the 15 per cent that come from bodies that were once largely molten. Three such igneous meteorites come from the surface of the Moon[1], eight may have come from Mars[2], and a large group — known as basaltic achondrites — may be pieces of 4 Vesta, the second or third largest asteroid[3,4]. But what is the origin of the variety of igneous meteorites known as stony-irons, which account for only seven per cent of falls of igneous meteorites but whose unusual mineralogy constitutes a major puzzle? New astronomical and theoretical studies indicate how and where the stony-iron meteorites may have formed in the asteroid belt.

Most igneous meteorites contain either less than 1% or greater than 99%, by weight, of metallic iron-nickel and other metallic phases. This is because the large density difference between molten iron and silicate ensures their rapid separation. By contrast, stony-irons usually contain 40–60 wt % iron-nickel (and always 20–80 wt %). In pallasites, the remainder is olivine $(Mg,Fe)_2SiO_4$, whereas in mesosiderites it is basaltic material, which lacks significant amounts of olivine.

How were large volumes of metal intimately mixed with massive amounts of mantle olivine or crustal basalts? For the pallasites, it is widely believed that metal from the core of a molten asteroid was forced into part of the surrounding olivine mantle as a result of cooling stresses, impacts and the weight of the mantle. But it is much more difficult to understand how mesosiderites formed. Petrological studies show that brecciated basaltic material from the surface of an asteroid was mixed with metallic iron-nickel without the inclusion of significant quantities of mantle olivine. At 1,000°C, the cooling rate of the mixture was about one degree per year but because the mesosiderites were eventually buried so deeply, their rate of cooling at 500°C was reduced by at least 10^5-fold and so was slower than that of any other type of meteorite.

Conventional models for the origin of mesosiderites attribute the mixing of metal and silicate to impacts between two igneously differentiated asteroids, and the slow cooling to subsequent accretion. However, R. Greenberg and C.R. Chapman[5] argue that the lack of olivine, the uniform cooling rates and the abundance of mesosiderites preclude such models and suggest instead that the mixing occurred within a single asteroid. In their scheme, a solid basaltic crust of a largely molten body sank towards the core-mantle interface when it was fractured by impacts because it was slightly denser than a liquid mantle beneath it. Liquid iron from the core penetrated the cold fractured blocks of crust so that the mixture cooled rapidly at high temperatures but much more slowly at low temperatures. Greenberg and Chapman suggest that pallasites formed in smaller bodies in which the olivine-rich mantles solidified before the crusts foundered.

Reviewing this and other proposed origins for mesosiderites, R. Hewins[6] concludes that no single model is wholly satisfactory. He finds that mesosiderite textures resemble those of rocks formed by impacts and believes that major collisions must have mixed metal and silicate. Hewins suggests that mesosiderites lack olivine because, unlike all known oxidized chondrites, their parent body never contained much olivine — an argument not favored by Greenberg and Chapman.

There has been no certain identification of asteroids with mesosiderite-like surfaces, although several S-type asteroids have been proposed as candidates. However, recent telescopic observations have revealed the existence of a new class of asteroids with surfaces that resemble those of pallasites. According both to D.P. Cruikshank and W.K. Hartmann[7] and to J.F. Bell and coworkers[8], infrared spectra of 246 Asporina, 289 Nenetta and 446 Aeternitas show the deep absorption bands of olivine and overall red colors that are consistent with the presence of a metal phase. Hence some asteroids of 50-100 km diameter have melted to form olivine-rich mantles that have since been exposed by collisional stripping of the crusts.

To learn more about the origins of mesosiderites and pallasites we must reach a much better understanding of the nature and distribution of the heat source, and of the movement of solid and liquid phases during melting and solidification. We need to know whether totally molten mantles of olivine-rich composition could be produced, and whether melting occurred after or during accretion in the asteroid belt. Theory and experiment will help to address these questions but to understand fully the origins of stony-irons we shall also need field studies of asteroids. □

Shiro Kakiuchi 1929–1984

SHIRO Kakiuchi of Osaka University Medical School, who died on 22 September, was a pioneer in many areas of cell regulation. During the mid 1960s he worked with T. E. Rall at Case Western Reserve in Ohio and made many contributions to cyclic nucleotide research during the formative years of this field. It was during this time that he began work on cyclic nucleotide phosphodiesterases. In 1970, soon after his return to Japan, Dr Kakiuchi revealed that a form of phosphodiesterase required the presence of an activator and that stimulation by the activator required Ca^{2+}-dependent protein activator that later came to be called calmodulin.

Kakiuchi realized the potential importance of the activator in other enzyme systems and in 1978 recognized that it was also the activator of myosin light chain kinases. Subsequently he isolated the protein from a variety of ciliates and invertebrates and discovered a calmodulin-dependent form of guanylate cyclase. In the same year, Kakiuchi found that calmodulin was partitioned between the soluble and particulate fractions of the cell, which led him to the discovery in 1980 that the only calmodulin-binding protein in the cytoskeleton of the red blood cell is spectrin. A year later he was the first to show the presence of a spectrin-like protein in other tissues and to purify the protein from brain. Also in 1981 he purified another calmodulin-binding protein from chicken smooth muscle and showed that it interacted with actin filaments.

This protein, which he called caldesmon, was subsequently named fodrin by US scientists. Caldesmon interacts with actin when the Ca^{2+} concentration is less than 1μM but with calmodulin at higher concentrations. This led to the hypothesis that calmodulin might control those proteins associated with actin in a 'flip-flop' mechanism depending on the Ca^{2+} concentration. The hypothesis was later extended to the Ca^{2+} regulation of microtubules when Kakiuchi showed that one of the microtubule-associated proteins, *tau*, was a Ca^{2+}-dependent calmodulin binding protein.

All of these experiments were pioneering efforts and each observation has been repeated and extended by numerous laboratories. As much as any one individual Shiro Kakiuchi was the father of the field of calmodulin research and an innovator in the study of its interaction with other regulatory proteins. He will be passionately missed by his many students, collaborators and friends. **A.R. Means**

Geomagnetic secular variation impulses

V. Courtillot & J. L. Le Mouël

Laboratoire de Géomagnétisme Interne et Paléomagnétisme (ERA CNRS 922), Institut de Physique du Globe, Université Paris 6 et UER Sciences Physiques de la Terre, Université Paris 7, 4 Place Jussieu 75230 Paris Cedex 05, France

The secular variation of the Earth's internal magnetic field changes on time scales of the order of a year. Such impulses occurred in 1969 and probably in 1913; they provide constraints on deep mantle conductivity, which appears to be rather low, and on the motions of the top of the fluid core, which are probably dominated by westward drift. Present data favour the existence of upwelling of core material at the core-mantle boundary. The impulses can be correlated with extrema in the Earth's rotation rate and interpreted in terms of electromagnetic core-mantle coupling.

THE study of temporal variations of the Earth's magnetic field has benefitted from observational advances in the past 5 yr. Secular variation of the geomagnetic field observed at the Earth's surface has been found to undergo rapid accelerations lasting less than a few years, a much shorter duration than had previously been recognized for signals generated in the Earth's core and having diffused through the electrically-conducting mantle. One such rapid and worldwide acceleration occurred in 1969; an earlier, less well documented, acceleration apparently occurred around 1913. The identification of these events was made possible by carefully assembled long data sets from magnetic observatories around the world. The centenary of the French Magnetic Observatory (St Maur-Val Joyeaux-Chambon La Forêt) provided the opportunity for a meeting to discuss recent progress on the origin and secular variation of the geomagnetic field. We now review evidence (in part presented at the meeting) for the occurrence of impulsive accelerations in geomagnetic secular variation. Also discussed are the implications of these events regarding deep mantle conductivity, their link with decade fluctuations in the rotation of the Earth, the case for core-mantle coupling and efforts to determine core motions.

Secular acceleration impulse of 1969

Short-period variations of the geomagnetic field are linked with electric currents flowing in the ionosphere and magnetosphere (thus having a primarily external origin), whereas longer-period variations are thought to be due to dynamo processes acting within the Earth's fluid metallic core. It was accepted until recently that the cutoff between the two was about 4 yr (see ref. 1). This cutoff was raised to more than 10 yr by Currie[2] and Alldredge[3], although it was recognized that signals with a clear external origin, such as the 11-yr solar cycle, fell close to this limit (see ref. 4). In a previous study[5] of observatory data for the period 1947-1972, we found no evidence for short-period signals that would have originated from the core. However, when attempting to separate the solar cycle from long-period internal variations, we noticed discrepancies in the correlation between variations seen on the horizontal versus vertical components, particularly between 1967 and 1972 (the date of the most recent data then available). These suggested that the effect could be due to a slight change in the second derivative of the 'true' internal secular variation. With data available up to 1977, it has been shown[6] that there had been an impulse in the third derivative of geomagnetic field components around 1969. The impulse was particularly spectacular in the east (Y) component of European observatories and was identified in at least 38 observatories from the Northern Hemisphere (Fig. 1).

Extremal secular variation behaviour had already been observed by Vestine[7] to have occurred around 1910. The concept of secular variation impulses was introduced by Walker and O'Dea[8], who found it convenient, for the purpose of correcting magnetic data to a given epoch, to approximate the secular variation by a constant value for a chosen interval. In this process, changes in constants from one interval to the next resulted in 'impulses'. These impulses were formerly attributed to the internal field (see refs 9, 10) but Alldredge[11] showed that the impulses were correlated with the sunspot cycle and resulted from an ill-chosen piecewise linear fit to the smooth external variations. We confirmed[5] that the slope breaks resulting in impulses coincided with extrema in the 11-yr variation.

The 1969 impulse is a completely different matter both in time evolution, geographical distribution and intensity, being an order of magnitude larger than the constructions of Walker and O'Dea. The original[6] presentation of the impulse was based on a representation of the field components themselves, which were interpreted in terms of two parabolic segments, with discontinuous curvature (that is second derivative) in 1969. This meant that the third derivative of the field components could be represented by a Dirac distribution. The parabolic representation was criticized by Alldredge[12] who suggested that the impulse might be an artefact of the fitting procedure. In response to this comment, Courtillot *et al.*[13] showed that displaying the data as first derivatives (computed simply from first-order finite differences) provided a very clear and convincing picture of the impulse (Fig. 1).

Parallel to the work done in Paris, a team led by Malin in Edinburgh observed, when preparing the 1975 World Magnetic Charts, the sudden change in secular acceleration of declination which occurred in 1969 in European observatories: Malin *et al.*[14] showed that the representation of secular variation as a function of time was to be preferred over that of the original data or of its second derivative. In the case of second-order finite differences, higher frequency noise is amplified together with harmonics of the solar cycle, in particular the harmonic with a period of 3.7 yr. Careful filtering can, however, reveal the step change in acceleration at the expense of time resolution (J. G. Gavoret, personal communication). Thus, together with Courtillot *et al.*[13], Malin *et al.*[14] concluded that data are well represented by a simple instantaneous change of slope between two linear segments and that the representation as "the sum of a series of sine curves of different frequency", proposed by Alldredge[12], "is an unnecessarily complicated and conceptually unhelpful way of regarding the phenomenon".

Working on first order differences for the X(north), Y and Z(vertical) annual mean values from 130 observatories, Chau *et al.*[15] and Le Mouël *et al.*[16] were able to confirm the worldwide and simultaneous character of the 1969 impulse. The amplitude of the step in the second time derivative was estimated from a least-squares fit of two linear segments to the data. The date of the impulse was determined by minimizing the r.m.s. residuals for impulse dates ranging from 1967 to 1972, and was found to be 1969. The worldwide distribution of impulse amplitude for each field component is shown in Fig. 2. Departure from the V shape in original observatory data may be due to remaining external signals, to problems in baseline control (up to 1970 most frequently in the Z component) and to more localized internal signals with a different behaviour, as is apparently the case under Central America and the Indian peninsula. In any case, the resulting picture is smooth and coherent.

Malin *et al.*[14] analysed the *D* (declination), *H* (horizontal intensity) and *Z* annual mean values for 184 worldwide observatories. They assumed that the magnetic field associated with the impulse was internal and performed a spherical harmonic analysis on 3-yr smoothed means, limiting the expansion to degree and order 6. Secular variation models were derived (by subtracting) for epochs 1963.5, 1965.5 and 1967.5, and for epochs 1971.5, 1973.5 and 1975.5, providing two estimates of secular acceleration, one centred on 1965.5, the other on 1973.5. Accelerations were derived by least-square fits of linear time functions to the secular variations, both before and after the impulse, and the resulting impulse amplitudes (1973.5 minus 1965.5 accelerations) truncated to degree and order 4 were given by Malin *et al.*[14]. The maps which can be derived from this truncated representation are in reasonable agreement with those of Le Mouël *et al.*[16], although differences exist. The largest amount of power in the Malin *et al.*[14] expansion is in the $n = 2$ terms. In a more recent analysis, Malin and Hodder[17] resumed the experiment for the components from 83 selected observatories, this time including the possibility for an external part in the field. The expansion was limited to degree and order 4. They found that most of the jerk is indeed of internal origin.

Inspection of the data from ref. 16 (see Fig. 2) reveals wide areas where the distribution of impulse elements are rather flat (such as central Asia for δX and δZ, or South America for δY) separated by narrow areas with steep gradients where sign changes occur (such as in northern Central America or South East Africa for δZ). Thus, an accurate description of the impulse distribution may require high-order spherical harmonics or a different representation; available data do not allow such a detailed expansion. However, the simplicity of the overall pattern demonstrated by the few and smooth zero-isolines of Fig. 2 favours the dominance of low (particularly $n = 2$) order terms[14,18].

Secular acceleration impulse of 1913

Following the identification of the 1969 impulse, it was natural to search for earlier occurrences of such a phenomenon that might have escaped identification. Vestine[7], for example, had noticed large changes in secular variation around 1910, and we noticed a sharp change in the secular acceleration of declination shortly after the beginning of this century at Val Joyeux ("Chambon"). Courtillot *et al.*[6] tentatively identify this event on the *Y* component of many observatories. Ducruix *et al.*[19] analysed annual mean values of *X*, *Y* and *Z* from 40 observatories in the Northern Hemisphere and 10 observatories in the Southern Hemisphere. They observed that for many observatories and many components secular variation roughly follows a linear trend between 1913 and 1969, which is preceded by a global break in the secular variation slope occurring around 1913 (Fig. 1). In certain areas, other internal variations of regional importance distort the simple piecewise linear (V) shape of the secular variation. Such is the case for the *Y* component in European observatories where an anomaly centred on 1925 renders the identification of the 1913 impulse more difficult. Ducruix *et al.*[19] outlined the zero isolines of the 1913 impulse for the three components. The geometry of the impulse is reminiscent of that for the 1969 impulse but with a reversal in sign. Secular variation may also have been linear between 1905 and 1913, but data for the early years of the century and last years of the previous century are too scarce, and sometimes too noisy, to allow a satisfactory global analysis of the event. The identification of impulses before 1910 is difficult. Only 19 observatories were in operation in 1900, 12 of them in western European countries. However, long homogeneous series of data such as that provided by Malin and Bullard[20] for London or that being prepared for Paris (J.L. Le M. *et al.*, in preparation) may help in searching for earlier events.

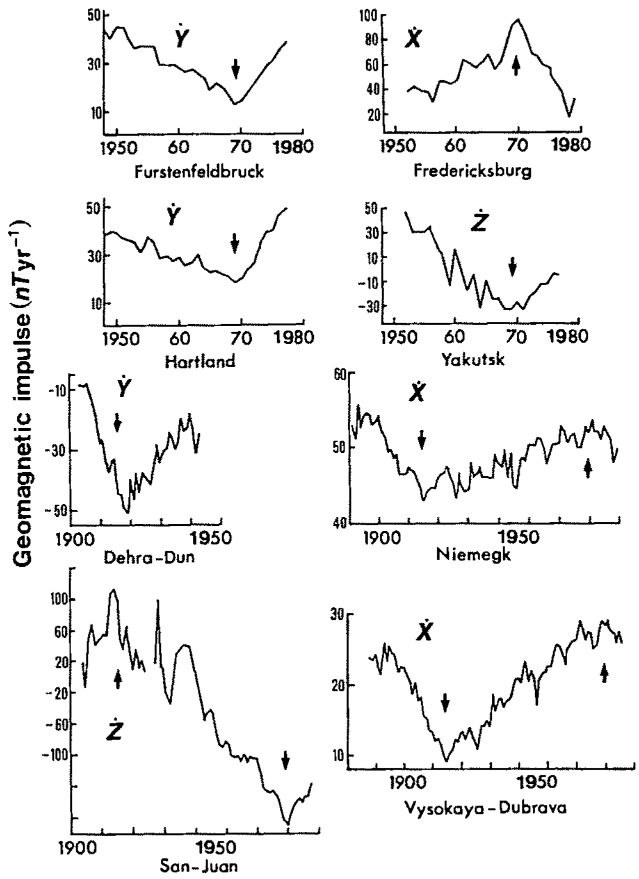

Fig. 1 Secular variation (first difference of annual mean values) of geomagnetic components *X*(north), *Y*(east) and *Z*(vertical) in widely-spaced observatories (from refs 13, 16 and 19). Furstenfeldbruck, Hartland and Niemegk are in Europe, Fredericksburg in the USA, Yakutsk and Vysokaya-Dubrava in the USSR, Dehra-Dun in India and San Juan in Puerto-Rico. The occurences of the ≈1969 and ≈1913 impulses are outlined by arrows.

Secular variation 1910–80

Ducruix *et al.*[19] and Gire *et al.*[18] conclude that the secular variation field can be modelled in a remarkably simple way from at least 1913; as a first approximation, each component of the secular variation can be represented as a two-segment broken line, with an apparently worldwide and synchronous break occurring in 1969 and probably an earlier one in 1913 (Fig. 3).

Using spherical harmonic coefficients provided by Hodder[21], Gire *et al.*[18] found that, between 1913 and 1969, the secular variation isovalue lines became wider apart and that the energy of secular variation was reduced by a factor 2. Between 1969 and 1980 the secular variation field recovered its strength and in 1980 the maps displayed strong similarities to those in 1912, except in the Far East where data are scarce. The linear model proposed by Gire *et al.*[18] accounts for more than 75% (in terms of energy) of the total secular variation observed for the *X* and *Y* components. Early values for the *Z* component are inaccurate and the piecewise linear model does not work as well.

Mantle conductivity

The classical way of probing the electrical conductivity of the Earth's mantle is to study transient geomagnetic variations of primary external origin and to separate the internal and external parts of the signal as it is observed at the Earth's surface (see ref. 22). The longer the period of the signal, the deeper its penetration depth. The identification of the solar-cycle variation and the separation of its internal and external parts have yielded some of the deepest estimates of mantle conductivity (down to ~1,500 km; refs 3-5, 23-28).

Another approach of the mantle conductivity problem uses the diffusion of magnetic signals generated in the Earth's core.

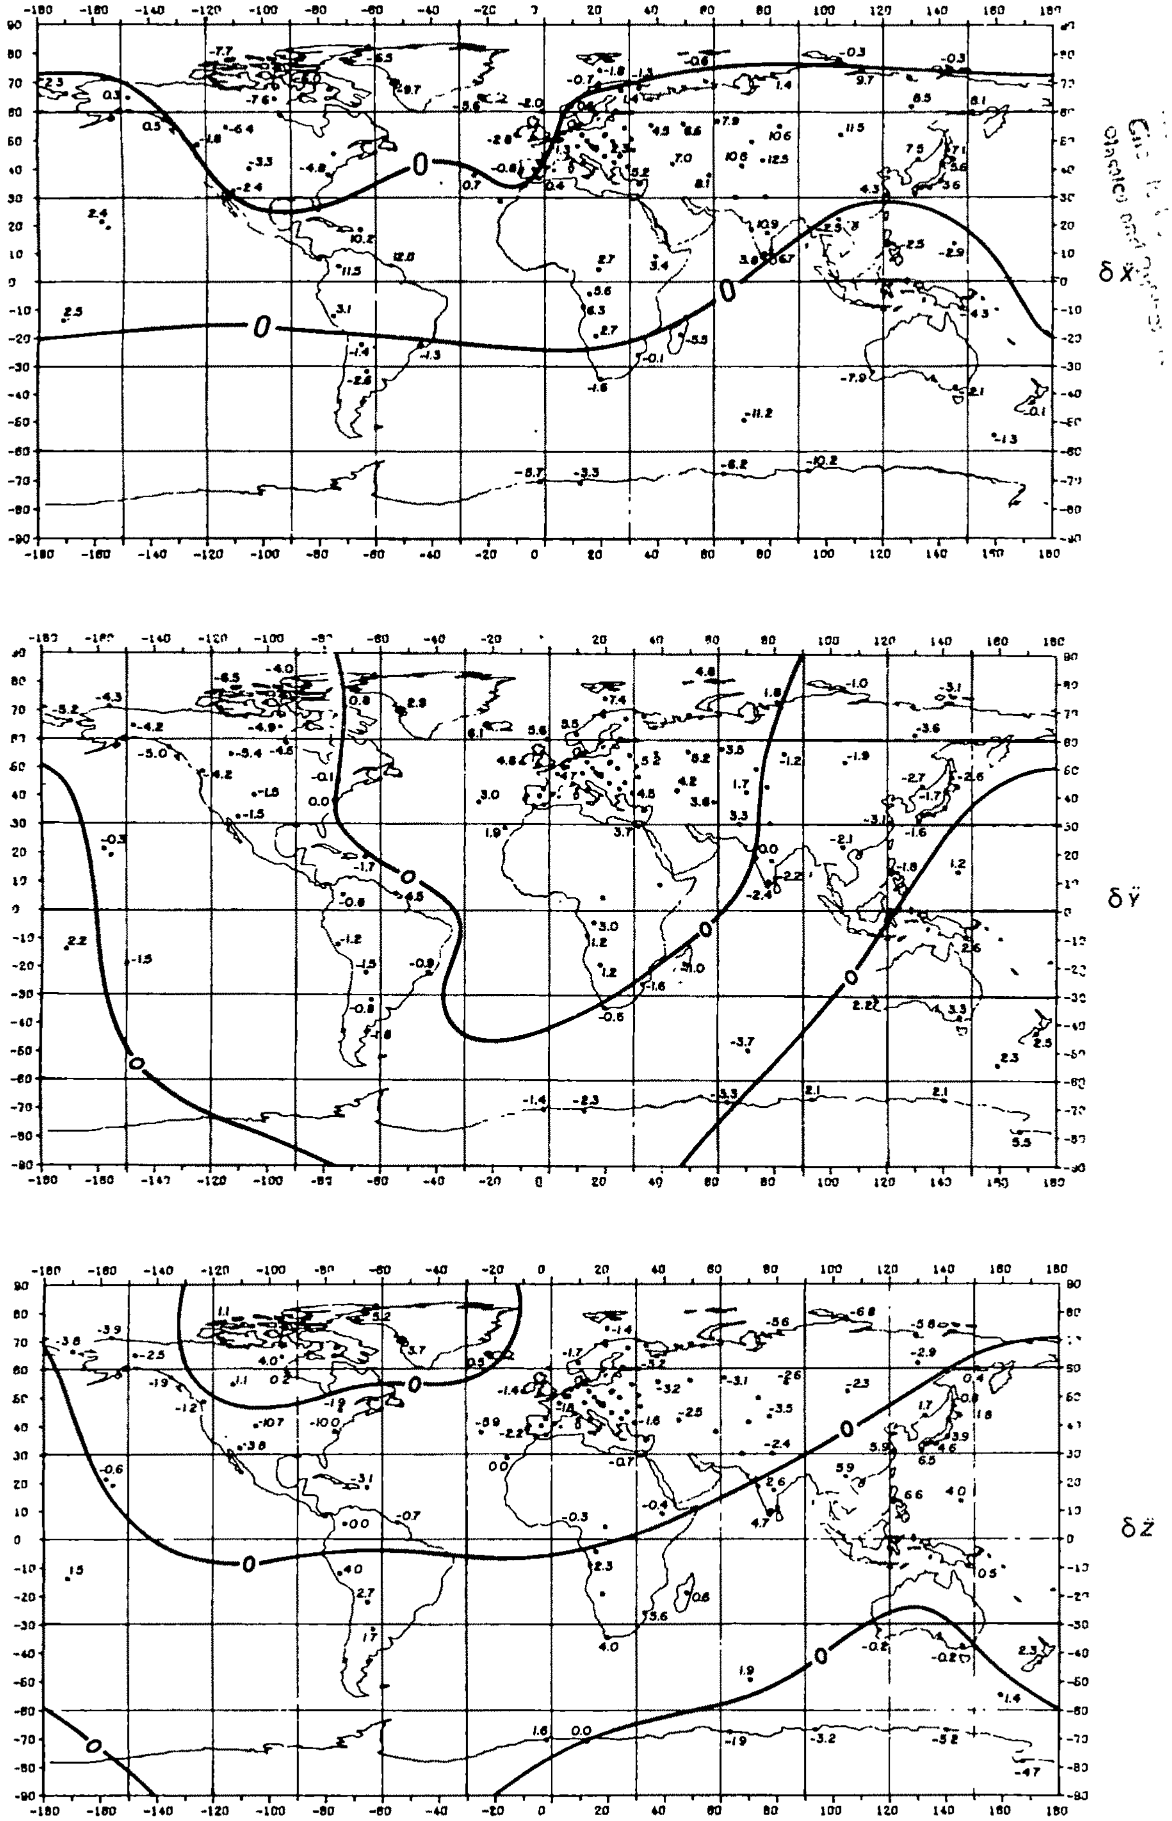

Fig. 2 Worldwide distribution of the $\delta\ddot{X}$, $\delta\ddot{Y}$ and $\delta\ddot{Z}$ components of the 1969 impulse with interpolated zero-isolines (in nT yr^{-2}, after ref. 16).

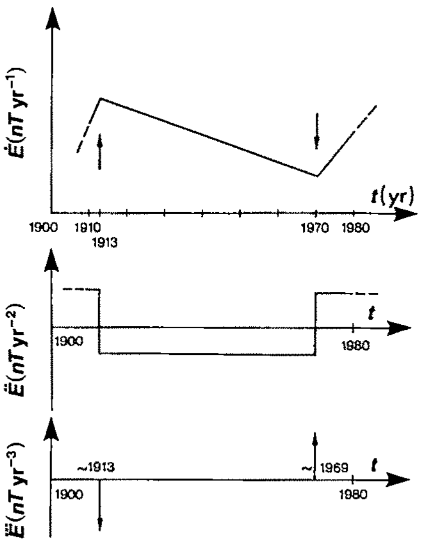

Fig. 3 A simple secular variation (first-time derivative) model for any geomagnetic element E involving two impulses in 1913 and 1969 and linear variations between the impulses. The second and third derivatives of E are also sketched.

Runcorn[9] used the "secular variation impulses" introduced by Walker and O'Dea[8] to infer an upper bound of the mean mantle conductivity, which he found to be of the order of $10^2\ \Omega^{-1}\ \mathrm{m}^{-1}$. McDonald[10] further studied the penetration of secular variation, including the 'impulses', through the mantle and derived a profile for the conductivity of the entire mantle, rising slowly from $30\ \Omega^{-1}\ \mathrm{m}^{-1}$ at 1,200 km depth to $200\ \Omega^{-1}\ \mathrm{m}^{-1}$ at the core-mantle interface. However, note that the impulses introduced by Walker and O'Dea are artefacts. Following the positive identification of the 1969 impulse, Achache *et al.*[29,30] resumed Runcorn's early analysis. These authors erroneously modelled the 1969 event as a second-order impulse, that is a step change in secular variation, and not acceleration[31]. The shape of the secular variation curves after 1969 was interpreted as part of the transient impulse response leading to a mean conductivity for the lower 2,000 km of the mantle of the order of $150\ \Omega^{-1}\ \mathrm{m}^{-1}$. This result was included in the global study of Achache *et al.*[28], who proposed a conductivity of the order of $300\ \Omega^{-1}\ \mathrm{m}^{-1}$ in the lower 700 km of the mantle.

Backus[31] has shown that when the radial component of the time-dependent magnetic field measured at the Earth surface is expanded in surface spherical harmonics, each spherical harmonic component of a given degree l observed at the surface is related to the same component at the Earth's core by a causal linear filter. Backus showed that the filter impulse response can formally be treated as a probability density function, whose mean τ_l and standard deviation σ_l are the delay time and smoothing time of the filter: the main effects of the lth mantle filter are to delay the input by τ_l yr and to smooth it in a gaussian way over σ_l yr. In principle, τ_l and σ_l can be evaluated from observations through spherical harmonic analysis, and thus they provide functions of (constraints on) mantle conductivity. Backus provided the way to apply mantle filter theory to an impulse of order p, that is, one for which the pth derivatives of geomagnetic components are Dirac distributions: if the impulse starts at the core surface at time t_0 and has an amplitude A_l, one can derive from the data the order p of the impulse, A_l, σ_l and $t_0+\tau_l$, but not t_0 and τ_l separately. Moreover, Backus stresses that each component of the field at a single location is a linear combination of the outputs for all degrees l and that if this composite signal is processed as if it were the output of a single filter, the resulting fictitious mixed filter can have a negative delay time τ_l and imaginary smoothing time σ_l. Applying the theory to the 1969 impulse as observed in Europe on the Y component (that is, the record on which the impulse was discovered and is particularly clear), Backus finds that $t_0+\tau = 1969.8 \pm 0.2$ (corrected from the original paper to account for the fact that annual mean values are centred on 1 July), $p=3$, $A = 5.0 \pm 0.3\mathrm{nT\,yr^{-2}}$ and $\sigma^2 = -2 \pm 1$ yr. Backus[31] concludes that harmonic mode mixing in Europe is probably responsible for the observed negative value of σ^2 (although a sunspot-related contribution or other source of noise remains a possibility). Even in the case where mode mixing does not occur, Backus remarks that the 1969 impulse permits values of σ as high as 2 yr with harmonics as high as order 4 and concludes that this is compatible with a lower mantle conductivity as high as several thousands of $\Omega^{-1}\ \mathrm{m}^{-1}$.

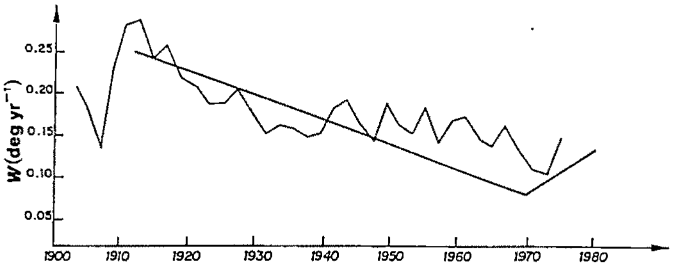

Fig. 4 Estimates of the westward drift rate computed for the period 1910–80 from a V-shaped model (straight lines, after refs 19 and 34) and using Hodder's[20,36] results (curved line).

Courtillot *et al.*[32] elaborated on Backus's[31] results and emphasized the fact that a sunspot-related signal could be responsible for the negative value of σ^2. They generated a synthetic curve, adding a typical sunspot signal to a pure third-order impulse, and found that the short data window available after the impulse indeed generated a sunspot related bias of σ^2, with a magnitude close to the observed one. Courtillot *et al.*[32] argued that the 1969 impulse is apparently worldwide and synchronous and that in many observatories, for many components, the transition from the pre-impulse to the post-impulse 'asymptotic' behaviour seems to take on the order of 1 yr. This led Courtillot *et al.*[32] to propose that harmonic mode mixing could be of minor importance.

Backus[31] showed that, for reasonable conductivity distributions, the ratio of smoothing time to delay time of a mantle filter has to lie between 0.3 and 0.8. Courtillot *et al.*[32] applied this constraint and pointed out that if σ, as they believe, is of the order of 1 yr, then τ must be <3 yr. Conversely, if the τ_l are indeed 13 yr, σ_l must be >4 yr (ref. 31 and G. Backus personal communication). Available data should allow a discrimination between $\sigma_l \leq 1$ yr and $\sigma_l \geq 4$ yr.

Using their preferred values of σ and the dominating spherical harmonic order $l=2$ of Malin and Hodder[17], together with Backus's[31] formalism, Courtillot *et al.*[32] pointed out that electrical conductivity must be $<300\ \Omega^{-1}\ \mathrm{m}^{-1}$ in 97% of the volume of the mantle. A precise determination of mantle filter coefficients will be required before any firmer statement can be made. The complex behaviour of the post-1970 solar magnetic effects (see ref. 27) and the poor geographical distribution of magnetic observatories may render a precise determination difficult.

Variations of westward drift rate

It has been known since the time of Halley (1692) that a significant part of the secular variation field can be accounted for by a westward rotation of the main field about the rotation axis of the Earth, known as westward drift (see ref. 33). Courtillot *et al.*[6] and Ducruix *et al.*[27] proposed that the 1969 impulse could be partly due to an enhancement of westward drift. Following Bullard *et al.*[33] and others, Le Mouël *et al.*[34] estimated the westward drift rate w by maximizing the contribution of the term $w\cdot\partial\mathbf{B}/\partial\phi$ (where ϕ is longitude) to secular variation $\dot{\mathbf{B}} = \partial\mathbf{B}/\partial t$. This estimate is:

$$w = \iint_S \dot{\mathbf{B}}\cdot\partial\mathbf{B}/\partial\phi\ \mathrm{d}S \Big/ \iint_S (\partial\mathbf{B}/\partial\phi)^2\ \mathrm{d}S$$

where the integrals are extended over the entire surface S of the Earth. Estimates can be made either directly from observatory data or spherical harmonic models of the fields **B** and $\dot{\mathbf{B}}$. In the last case, one can use the whole field or a single component[34]. Although results obtained with spherical harmonics were inaccurate and oversmoothed in time, they revealed a consistent pattern of decreasing westward drift from 1955 until 1970–75, increasing since then. Results were clearer with the raw observatory data, where the w variation displayed the characteristic V shape of the original recordings, with a minimum around 1970. The analysis was pushed further by Gire *et al.*[35] who used Hodder's[36] secular variation coefficients (Fig. 4). Gire *et al.* computed the energy spectrum of the geomagnetic field at the Earth's surface and noted that, regardless of the component being used to estimate w, the major contribution to this estimate came from multipoles with degree <4. The dominant contribution was found to come from the quadrupolar term P_2^2, as already discussed, for instance, by Yukutake[37], and to a lesser extent from P_2^1. Gire *et al.* further noted that estimates of w based respectively on Y, B, Z and X were always in the order $w_Y > w_B > w_Z > w_X$. They suggested, based on numerical experiments on existing field and secular variation models, that all these estimates were smaller than the actual w and that Y provided the best estimate. Errors on w_Y estimates in the numerical experiments were of the order of 20%.

The results (Fig. 4) confirm the regular decrease in w from 1950 to 1970, already pointed out by Harwood and Malin[25]. The decrease started around 1913 as shown by Hodder[36], and Gire *et al.*[18]. The increase that started in 1970 has now brought the westward drift rate back to its 1950 value.

Motions in fluid core

Secular variation and, in particular, westward drift may provide information on fluid core motions. To extract that information, *a priori* knowledge of the electrical conductivity of the core material is required. This conductivity is estimated to be of the order of 10^5–$10^6\ \Omega^{-1}\ \mathrm{m}^{-1}$ (see ref. 38), that is $\sim 10^3$–10^4 times larger than the estimated conductivity of the lower mantle. On the decade time scale, which is typical of secular variation, the core material is actually often considered to be a perfect conductor. Voorhies and Benton[39] have recently shown with MAGSAT data that this is an excellent approximation. In that case, the secular variation observed outside the core depends only on the motion **U** at the core-mantle boundary[40] (CMB), more precisely at the surface of the main stream of the upper core just below a transparent boundary layer[41]. Under this so-called frozen-flux approximation[41,42], the lines of force of the magnetic field are advected by motions at the surface of the main stream of the core. Many authors propose that the geomagnetic westward drift is due to the drift of the outer core layers with respect to the mantle. It is then tempting to associate secular variation impulses with corresponding impulses in the drift rate of the outer core. Another suggestion put forward by Hide[43–46] is that westward drift could be due to magnetohydrodynamic waves in the liquid core.

The horizontal velocity field at the CMB can be written as a sum of toroidal terms and of poloidal terms which characterize upwelling, that is exchange of material with the deeper regions of the core. The first toroidal term $t_1^0\theta_1^0$ characterizes the body rotation part of westward drift. The equation which relates **B**, $\dot{\mathbf{B}}$ and **U** is:

$$\dot{B}_r = -\mathrm{div}_S(B_r\mathbf{U}) \qquad (1)$$

where div_S is the surface divergence operator $(\nabla - \mathbf{r}(\mathbf{r}\cdot\nabla))$. Since the relative change in **B** is comparatively small in the time interval of decades considered here, we might indeed expect that secular impulses in $\dot{\mathbf{B}}$ be related to similar accelerations of **U**. To continue B_r and $\dot{B}_r$ downward from the surface of the Earth to the CMB, one often assumes that the mantle is a perfect insulator. Although this is clearly not the case, the mantle conductivity is sufficiently weak not to distort the core field significantly. Benton *et al.*[47,48] and Whaler and Gubbins[49,50] have continued B_r and $\dot{B}_r$ to the CMB under the assumption of an insulating mantle. Benton and Whaler[51] investigated the effects of the weakly-conducting mantle using a perturbation procedure and found that, at present, the errors in the core fields due to uncertainties in the higher-order terms of the surface field models are larger than the perturbations due to finite conductivity. Backus (ref. 31 and personal communication) has shown that, provided the delay time τ_l is about the same for individual modes, downward continued maps of B_r and $\dot{B}_r$ at the CMB actually describe the field there as it was τ_l yr before the time when geomagnetic variations occurred at the Earth surface.

Backus[42] showed that the determination of **U** from **B** is an ill-posed problem and that if one solution can be found, an infinity of other solutions can be built from it. However, several authors have recently attempted to use the rather simple and well-organized pattern of secular variation to estimate **U** using additional restricting assumptions.

Whaler[52] used equation (1) only at extrema of B_r on the CMB. She noted that if the upper core is stably stratified, that is, if there is no poloidal component in $\mathbf{U}(\mathrm{div}_S\mathbf{U} = 0)$, then these extrema must be points at which $\dot{B}_r$ is zero. Using the 1965.0 IGRF model ($N = 8$), Whaler noted that ($\dot{B}_r = 0$) contours pass remarkably close to extrema of B_r. She used a statistical argument to suggest that this observation is significant, implying a stably stratified layer at the top of the core. In more recent work, Whaler uses linear inverse theory in an attempt to estimate integrals of $\dot{B}_r$ inside spherical caps bounded by (B_r = constant) contours (ref. 53 and personal communication). With 318 data points from well-distributed long running permanent observatories, she finds that the error due to imperfect resolution far exceeds that due to mapping of the original data into the solutions and that a considerably larger data set would be needed to decide whether the core velocity field is purely toroidal. This conclusion is independantly sustained by work done by Benton *et al.*[48]. These authors show that the shape of null-flux curves ($B_r = 0$ contours) and the number and locations of critical points of B_r are a sensitive function of the truncation level of the spherical harmonic expansion.

Madden and Le Mouël[54] and Gire *et al.*[35] also expanded $\dot{B}_r$ in spherical harmonics at the CMB under the assumption of an insulating mantle and derive (from equation (1)) the linear equations which relate observations **b** (the vector of coefficients of the $\dot{B}_r$ spherical harmonic expansion) to the unknowns **u** (the vector of coefficients of the **U** expansion in elementary poloidal and toroidal harmonics modes):

$$\mathbf{D}\cdot\mathbf{u} = \mathbf{b} \qquad (2)$$

Alternatively, the data can be values of secular variation components at several observatories (140 in Madden and Le Mouël[54] analysis). Gire *et al.*[35] use both a generalized inverse approach[55,56] and a stochastic inverse approach[57] to solve equation (2). To reduce the fundamental non-uniqueness in the problem, both Madden and Le Mouël[54] and Gire *et al.*[54] restrict **U** to be a simple regular motion by damping the higher degree terms of the truncated expansion.

Gire *et al.*[35] concluded that the t_1^0 estimate is stable (stability being defined mathematically) and clearly dominates other terms. The estimate of the drift rate of the outer core layers is of the same order as values computed from observations of geomagnetic westward drift made at the Earth's surface. Estimates for t_1^0 in 1980 are between 0.15 and 0.20° yr^{-1} and are systematically higher than estimates in 1970 (between 0.05 and 0.10° yr^{-1}): this acceleration is thought to be linked with the 1969 impulse. This result had not been obtained in the earlier analysis of Madden and Le Mouël[54]. More recently, Gire *et al.* (personal communication) have extended the discussion to higher-order terms, and found that no term of degree higher than four is stable. Gire *et al.* constructed poloidal and toroidal motion models from these stable terms (Fig. 5) and found that between 1970 and 1980 the shape of the toroidal motion (clearly dominated by westward drift) does not change much but that its intensity increases by 70%. In contrast, the geometry of poloidal motions is different. The motion, which had slowed down in 1970, had returned to a stronger, more energetic state

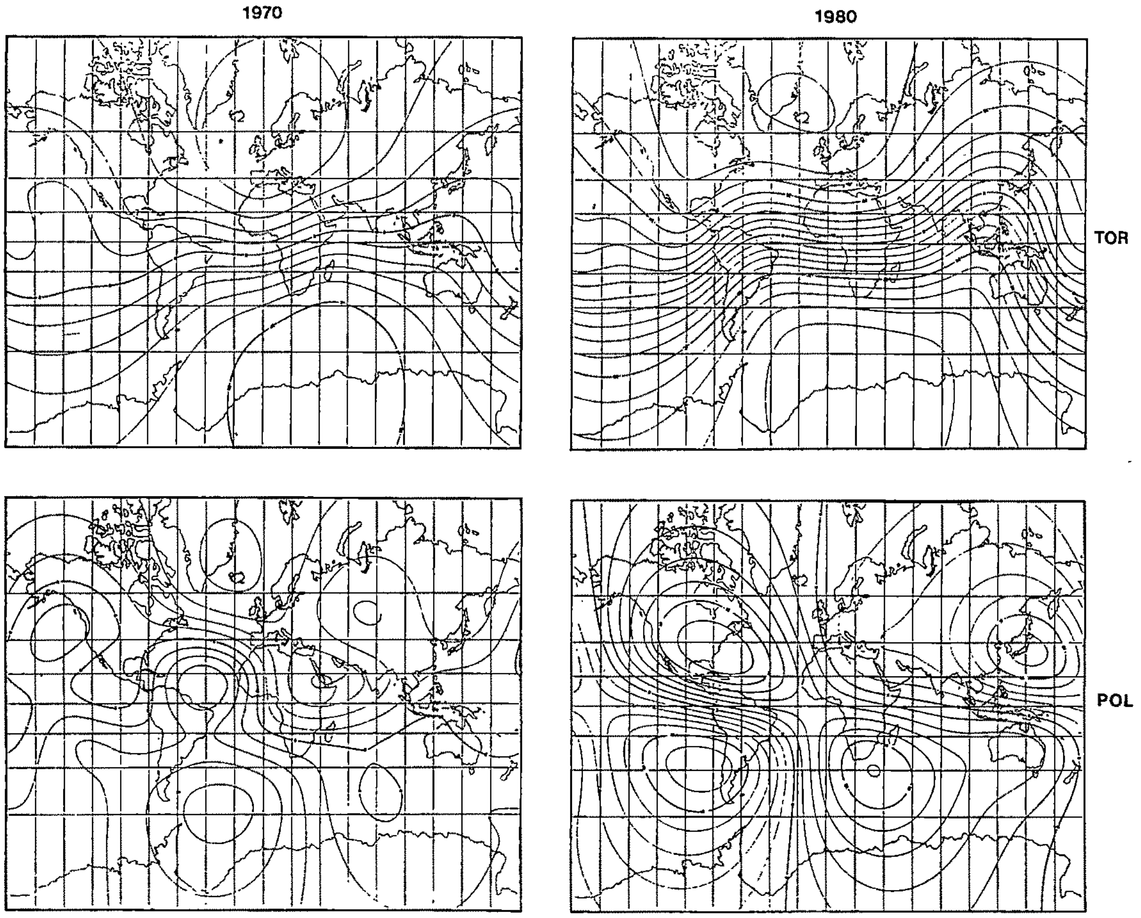

Fig. 6 Stable toroidal and poloidal motion models of Gire *et al.* (personal communication) for 1970 and 1980.

in 1980, the energy input probably being related to the 1969 impulse. Gire *et al.* are able to generate the observed secular variation field from either a purely poloidal or a purely toroidal motion, but this requires harmonics with considerably higher degree and much more energy than the low degree stable composite (toroidal + poloidal) motion. Whaler (personal communication) did not find an acceptable purely toroidal velocity field that would satisfy the surface geomagnetic secular variation data. Velocity fields which satisfied the original data to within their errors had considerable short-wavelength motion that could not possibly be resolved by the data. They were also unstable in the sense that small changes in the misfit between data and model produced very different velocity models.

Thus, parallel studies of recent geomagnetic secular variation suggest that the upper core is not stably stratified and that fluid upwelling exists at the CMB. Even if one is not yet ready to accept the velocity models of Fig. 5 as having actually something to do with real motions, these motions can still be considered as (in a way) the simplest phenomenological representation of the secular variation field.

Rotation of Earth

An up-to-date discussion of the Earth's rotation, in particular of its irregularities, has recently been given by Lambeck[58] (see also ref. 59). Hide[44] summarizes aspects of the problem that are relevant to atmosphere-mantle and core-mantle coupling. Small irregular changes in the rotation rate (or corresponding length of day, l.o.d.) can be attributed in part to atmospheric circulation: Hide *et al.*[60] and Barnes *et al.*[61] have shown that observed short-term changes in l.o.d. (with a period less than a few months and perhaps up to 1 yr) can be fully accounted for on the basis of angular momentum exchange of the mantle and atmosphere. On the other hand, the observed changes in l.o.d. of up to 5 ms on the decade time scale[62] cannot be associated with atmosphere-mantle coupling[58]. There is a general consensus that these variations originate in the Earth's core in relation to geomagnetic field generation and electromagnetic or mechanical core-mantle coupling. Hide[44] reviews the magnitudes of three kinds of horizontal stresses that couple the core to the mantle finding that viscous coupling is almost certainly inadequate. Electromagnetic coupling is sufficient (provided available estimates of relative electrical conductivities and field intensities are correct), although topographic coupling due to bumps on the core-mantle interface of about 1 km in height may be important[45,46]. Therefore, we may expect to find a correlation between geomagnetic indicators and changes in l.o.d. in the decade period range which is typical of secular variation. Vestine[7] was probably the first to give evidence that such a correlation might exist.

The discovery of the 1969 geomagnetic impulse has revived this topic. Courtillot *et al.*[6] noted a striking proximity between periods of intense secular acceleration changes, particularly impulses, and extrema in the l.o.d. variations. Le Mouël *et al.*[63] compared the secular variation of D in Europe and l.o.d. (with a sign error in their figure, see ref. 64) over the past 120 yr, and found a good correlation, with l.o.d. variations lagging geomagnetic variations by 10–15 yrs (Fig. 6). Le Mouël *et al.*[63] have suggested that secular variation impulses near 1900 (?), 1913, and 1969 should be linked with extrema of the l.o.d. curve near 1910, 1930 and 1980 (?): increased (decreased) westward drift is followed by increased (decreased) rotational velocity of the Earth. This correlation is the opposite of that proposed by Vestine[7], Runcorn (ref. 65 and personal communication) and more recently by Backus[31]. Backus has pointed out that Morrison's[62] l.o.d. data indicate that the angular position of the mantle suffered an impulse of order 3 in 1956 and suggested that both this event and the 1969 geomagnetic impulse may be caused by an impulse in westward drift: in that case, the magnetic effects would lag the rotational effects by some 13 yr, an increase in westward drift following a decrease in rotational velocity.

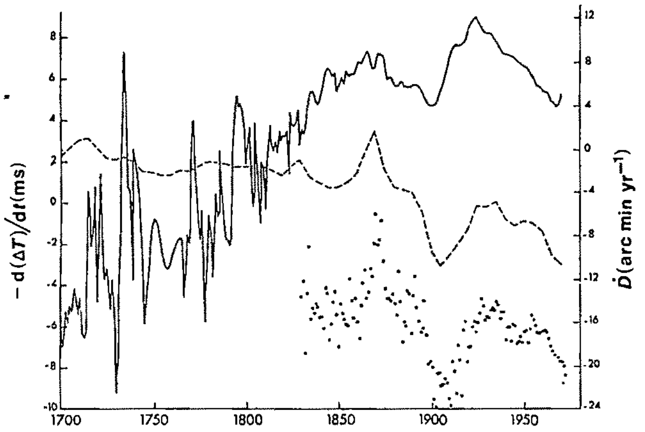

Fig. 6 Plot of the secular variation of declination $\dot{D}$ at Chambon La Forêt (solid curve) and of the excess length of day $-d(\Delta T)/dt$ (ref 62) (dashed curve) for the period 1700-1972 (see refs 63, 64 for the sign correction which is included here). Dots are annual means of excess l.o.d. from which the smooth dashed curve is derived[62]. For clarity they are displaced by 5 ms.

One way to assess the correlation is to investigate whether it extends back in the past. As already pointed out, the number of available observatories before 1900 is limited, but a preliminary analysis of the 1700-1870 period (ref. 63 and J.L. Le M. *et al.*, in preparation) seems to indicate that this was a time with no dramatic geomagnetic changes, no large accelerations of westward drift, and also no large changes in the acceleration of the Earth's rotation (Fig. 6). It may then be tentatively suggested that the correlation still holds qualitatively and that the eighteenth and nineteenth centuries were times when the core regime was more stable than in the present century.

Models of core–mantle coupling

Simple models of mechanical and electromagnetic core-mantle coupling can be constructed in an attempt to account roughly for the magnitude of l.o.d. and westward drift variations and for the correlation which is assumed to link the two. If one accepts the correlation which is suggested by Backus and Vestine, the fact that changes in westward drift rate follow l.o.d. changes and are of the same sign can be understood if one assumes convective mass exchange between a thin rigid shell, forming the top of the core, and the rest of the liquid core below it (called here a three-layer model). This model is similar to that originally proposed by Bullard[66] and later extended by Rochester[67]. The radial mass exchange exerts a torque on the outer core and (in the case of 1956 l.o.d. event studied by Backus) decelerates it. Electromagnetic coupling at the CMB in turn decelerates the mantle. The changes in rotational velocity of the mantle would immediately show as l.o.d. changes (a second-order impulse in mantle angular velocity in 1956), and be followed by geomagnetic changes, observed with a 13-yr mean delay due to diffusion of westward drift related signals through a rather strongly conducting mantle[31].

If, on the other hand, one follows the correlation suggested by Le Mouël *et al.*[63], one has to account for the discrepancy between the short time scale over which the geomagnetic impulse is established (1 yr) and the long delay after which the rotation of the mantle is altered (10-15 yr). We have also used a three-layer model[68], in which an impulsive torque (P) related to core convection is applied to the top core layer and a torque ($-P$) to the rest of the liquid core. When the torques exerted by Lorentz forces on the three part of this electromagnetic system are computed, a linear differential system for the rotations of the mantle and of the top and rest of the liquid core results. We[68] found that the solutions of this system depend exponentially on two time constants, one always short (<1 yr) and the other proportional to the ratio σ_c/σ_m of the core versus mantle conductivity. If this time constant can be identified with the 10-15 yr delay in changes of l.o.d., σ_c/σ_m is found to range from 500 to 1,000, in agreement with conductivity estimates discussed above. For (P) a first-order impulse (that is a step function), the l.o.d. suffers a second-order impulse, and the ratio $(\delta\omega_m)/(\delta\omega_0)$ of asymptotic amplitudes of rotational changes in the mantle and outer core layer following the impulse is found to depend only, in a first-order approximation, on the ratio of the outer core layer thickness h to the total core radius r_c. We found h to be of the order of 150 km. The radial velocity of fluid exchange between the outer and inner parts of the external core was found to be $\sim 10^{-6}$ ms^{-1}. Although this model provides a reasonable account for observations discussed by Le Mouël *et al.*[63], it is limited in that it does not include a quantitative treatment of magnetic field transport, particularly from the outer-inner core interface to the CMB. Thus, both an improved assessment of the l.o.d./geomagnetic correlation and more complete models of electromagnetic core-mantle coupling are required.

Runcorn (ref. 65 and personal communication) argues that irregular changes in l.o.d. may even be shorter than the present smoothing of the astronomical data indicates. If such impulsive torques indeed act on the mantle to provide changes in l.o.d., Runcorn points out that equatorial components of these torques may exist and excite the Chandler wobble. He proposes that such an impulse occurring in mid-1967 in the Chandler wobble supports this idea. It is not clear whether this event can be causally related to the 1969 geomagnetic impulse. On the other hand, Barnes *et al.*[61] showed that meteorological phenomena provide an important contribution to the excitation of polar motion.

Both Runcorn (personal communication) and Backus (ref. 69 and personal communication) note that the magnetic variations related to the 1969 impulse should be accompanied by a second-order impulse in the tangential component of the electric field on the ocean bottom, with an amplitude of the order of 10^{-8} Vm^{-1} yr^{-1}. Runcorn and colleagues (personal communication) have observed the occurrence in 1969 of step-like increases of d.c. potentials on long telegraph cables in the southwestern Pacific. These might arise from leakage currents associated with the core magnetic field and might be related to the geomagnetic impulse (Runcorn *et al.* in preparation).

Conclusion and perspectives

The reality of short-term (quasi-discontinuous) changes in the rate of internal geomagnetic secular variation has been confirmed by observational evidence in the past few years. The last worldwide impulse occurred in 1969 and may have been preceded by an event in 1913. The duration (of the order of 1 yr), intensity and geographical pattern of these impulses constrain values of deep mantle conductivity and the pattern of flow in the upper part of the fluid core. We suggest a correlation of geomagnetic westward drift and the l.o.d.; this correlation is still debated but would place important constraints on mechanisms of core-mantle coupling. It has also been proposed[70] that decade fluctuations of climate and l.o.d. are both correlated with geomagnetic changes, thus raising the possibility of a long-term influence of core motions on some climatic trends. In this process, angular momentum would be transferred from the core to the mantle and to the atmosphere.

Theoretical work[31] indicates the need for further observational work on both recognized impulses and earlier (seventeenth to nineteenth century) events, although the data base is scarce. Present data favour the existence of upwelling in the fluid upper core. Secular variation models which involve impulsive events separated by quiet phases are simpler, both in space and time, than previously expected and yet account for much of the energy of observed secular variation.

Progress on dynamo theory in coming years might be expected to come from detailed observational advances of two basic features of the geomagnetic field: impulses and reversals. The frozen-flux approximation, which is valid for impulses, might be extended to the 1,000-yr time scale which characterizes reversals. Much progress has been made on the description of individual reversals (see refs 71-73) and on the frequency of reversals (see refs 74, 75). The interests and frequency bands of specialists of geomagnetism and palaeomagnetism are converging in this endeavour.

This paper reviews published work on geomagnetic impulses and contributions to a meeting held on 27 September 1983 at the Institut de Physique du Globe in Paris on the occasion of the centenary of the French National Magnetic Observatory. Our review has greatly benefited from oral presentations made at the meeting, and from written communications sent after the meeting by G. Backus, R. Hide, W. Lowrie, T. Madden, S. Malin, K. Runcorn and K. Whaler. The meeting and paper are dedicated to the observers in magnetic observatories whose painstaking and often ill-recognized efforts in gathering data are essential for the kind of work described here. IPGP contribution NS793.

Note added in proof: M. McLeod (personal communication) has completed a detailed response to Alldredge's criticism[17] which fully vindicates our analyses[6,13] and those of Malin *et al.*[14,17]. The following conclusions from McLeod's work are worth noting: (1) The 1969 impulse is clearly real and of internal origin. The external coefficients of the s.h. expansion[17] appear to represent noise due to external currents unrelated to the impulse. Better estimates of internal s.h.c. are obtained. (2) The 1969 impulse can be as short as 1 yr in duration and its date of occurrence is found to be 1969.5.

Cell type-specific activation of actin genes in the early amphibian embryo

T. J. Mohun, S. Brennan, N. Dathan, S. Fairman & J. B. Gurdon

CRC Molecular Embryology Research Group, Department of Zoology, University of Cambridge, Downing Street, Cambridge CB2 3EJ, UK

Muscle actin genes are the earliest yet described to show cell type-specific activation in amphibian embryos. Gene-specific probes show that α-skeletal and α-cardiac actin genes start to be transcribed simultaneously at the end of gastrulation, but only in those regions of the mesoderm that subsequently form embryonic muscle. Their expression provides a molecular marker for early cell determination.

WITHIN a day of egg fertilization, most animal embryos comprise many morphologically distinct tissues and organ primordia, the arrangement of which remains essentially unchanged throughout all subsequent development[1]. In each region of the embryo, cells initiate distinct programmes of gene expression as they embark on diverse pathways of differentiation, the basic body plan of the embryo being laid down from the earliest times. As yet, however, almost nothing is known of the molecular mechanisms that underlie regional differences in cell fate within the early embryo. Classical theories suggest that the spatial pattern of early cell differentiation reflects the distribution of cytoplasmic factors or 'determinants' inherited by the early *a*

* consensus actin sequence for vertebrates

boxes indicate diagnostic amino acids

b

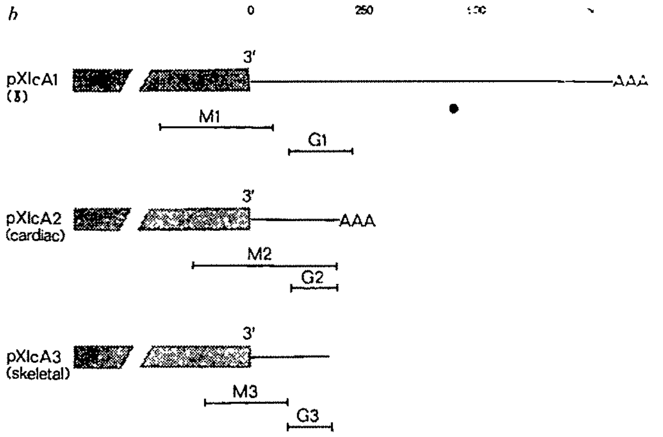

Fig. 1 Identification of *Xenopus* actin cDNAs. *a*, Portions of the nucleotide sequence for three *Xenopus* actin cDNAs, pXlcA1, pXlcA2 and pXlcA3, obtained using the dideoxy sequencing procedure[32,33]. These are aligned by comparing their coding capacity with the consensus polypeptide sequence of vertebrate γ-cytoskeletal and α-cardiac actins[9-13]. Amino acids diagnostic for particular actin protein types are boxed. Diagrams of each cDNA are shown in *b*. Amino acid coding regions are indicated by stippling. Subclones used in subsequent experiments are identified; M1, M2 and M3 contain the 3' terminal portions of protein coding sequence and an adjacent region of the untranslated mRNA trailer. These were used for S_1 nuclease protection experiments. G1, G2 and G3 comprise subclones for the mRNA 3'-untranslated region and provided gene-specific hybridization probes in RNA blot experiments.

blastomeres[2], but few of these have been demonstrated in any organism and none has been purified. The nature of determinants and the manner by which they regulate cell differentiation remain central problems for embryologists.

As a prerequisite for a molecular analysis of embryonic cell differentiation we have examined the expression of the actin multi-gene family in the amphibian embryo. It is well established that among vertebrates the several actin proteins are distributed in a tissue-specific manner[3,4]. The cytoskeletal actins are ubiquitous, whereas the sarcomeric actins are found only in muscle cells where they constitute a major component of the contractile apparatus. In amphibians, the morphological differentiation of cells that give rise to embryonic muscle occurs soon after neurulation[5,6] and the onset of muscle actin protein synthesis[7]. We report here that activation of amphibian α-cardiac and α-skeletal actin genes is coordinated at the end of gastrulation. Using mRNA-specific probes derived from *Xenopus laevis* α-cardiac, α-skeletal and γ-cytoskeletal actin cDNAs, we find that activation of both muscle-specific genes is precisely localized to certain regions within the mesoderm. In contrast, cytoskeletal actin gene transcription can be detected throughout the entire embryo.

Characterization of actin cDNAs

cDNA libraries from embryo RNA and adult skeletal muscle RNA were constructed as described elsewhere (T.J.M. *et al.*, in preparation) and screened for actin cDNA sequences using a chick β-actin cDNA[8] as probe. The entire DNA sequence of several positive recombinants was determined to establish the amino acid sequence of the actin that each cDNA encoded. Amongst vertebrates, the two cytoskeletal (designated β and γ) and four sarcomeric actins (α-cardiac, α-skeletal and two smooth muscle types) may be identified by characteristic differences in their polypeptide sequence[9-13]. Using these diagnostic differences, we obtained a tentative identification of three *Xenopus* cDNAs, pXlcA1-3. pXlcA1 codes for a protein identical to the consensus for vertebrate γ-cytoskeletal actins (Fig. 1*a*). Unlike other vertebrates, amphibians possess a variety of cytoskeletal actins that differ from both β-type and γ-type proteins[14]. pXlcA1 encodes the protein previously identified as 'type-8'. pXlcA2 and pXlcA3 match the consensus for muscle-type actins, pXlcA2 coding for α-cardiac actin and pXlcA3 encoding the related α-skeletal actin.

In addition to determining the coding capacity of each cDNA, we have examined the untranslated portions of their sequence (T.J.M. *et al.*, in preparation). We find no homology between any of the three cDNAs in their 3'-untranslated regions; therefore we constructed mRNA-specific hybridization probes for subsequent experiments (Fig. 1*b*).

Tissue-specific expression of actin mRNAs

We next sought the *in vivo* identity of the three actin cDNAs by determining in which adult tissues their equivalent mRNAs could be detected. RNA from a variety of adult frog tissues was hybridized with individual actin mRNA-specific single-stranded DNA probes M1, M2 and M3, derived from the cDNAs pXlcA1-3. Each probe, comprising several hundred nucleotides, includes the carboxy-terminus of the actin protein as well as a portion of the adjacent message-specific 3′-untranslated region subcloned into ml3mp8. Individual actin mRNAs were identified by the size of the S_1 nuclease-resistant fragments obtained (Fig. 2). As expected, the two muscle-type actin transcripts show distinct, tissue-specific patterns of expression consistent with the amino acid sequences they encode. mRNA corresponding to pXlcA2 is found exclusively in heart tissue (Fig. 2*a*), whilst the message-specific probe from pXlcA3 identifies transcripts only in skeletal muscle (Fig. 2*b*). We conclude that the clones pXlcA2 and pXlcA3 comprise α-cardiac and α-skeletal actin cDNAs respectively. The S_1 nuclease assay shows that α-cardiac and α-skeletal actin mRNAs are at least 50 times less abundant (if present at all) in non-muscle tissues. An equivalent survey demonstrates the presence of cytoskeletal actin transcripts complementary to pXlcA1 in all adult tissues examined (data not shown).

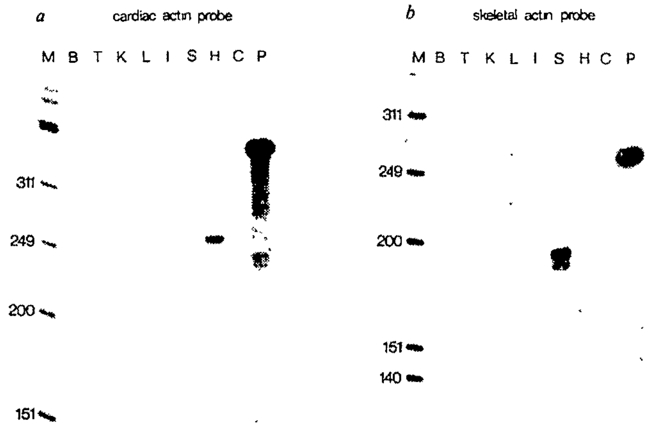

Fig. 2 Tissue-specific expression of actin genes. *a*, 250-nucleotide fragment obtained by protection of the α-cardiac probe M2 by α-cardiac mRNA; *b*, doublet of 185 and 190 nucleotides obtained by protection of the α-skeletal actin cDNA probe M3 by α-skeletal actin mRNA. RNA was prepared from various adult frog tissues and hybridized separately to the two probes M2 and M3 (see Fig. 1). DNA protected from subsequent digestion by S_1 nuclease was analysed by electrophoresis. The source of each RNA sample is indicated. B, brain; T, testes; K, kidney; L, liver; I, intestine; S, leg muscle; H, heart. Lanes 'P' and 'C' are controls using yeast tRNA for the hybridization, before and after S_1 digestion respectively. Size markers were provided by ΦX174 RF DNA digested with *Hin*fI (lane M). Each of the probes M2 and M3 contains 55 nucleotides of M13 sequence which is removed from all DNA/RNA hybrids by S_1 nuclease action. Protected fragments resulting from hybridization of the probes to their corresponding mRNAs are therefore significantly shorter than the input probes. The α-cardiac cDNA pXlcA2 contains an internal polyadenylation signal sequence 91 nucleotides upstream from the poly(A) tail (T.J.M. *et al.*, in preparation); our unpublished experiments indicate that this first polyadenylation signal predominates in transcript processing. Polyadenylation mostly occurs about 15 nucleotides downstream from this first pentanucleotide AAUAA and about 70 nucleotides upstream of the second polyadenylation site. Hence protection of the α-cardiac probe M2 (381 nucleotides) by α-cardiac mRNA yields a 250-nucleotide fragment (*a*). In addition, several fragments approximately 120–130 nucleotides long are protected by α-cardiac actin mRNA (not included in *a*, see Fig. 6). Experiments using end-labelled probes have demonstrated that these result from internal S_1 nuclease cleavage over a region of about five nucleotides in the middle of the actin cDNA portion of probe M2. Protection of the α-skeletal actin cDNA probe M3 (247 nucleotides) by α-skeletal actin mRNA results in a doublet of 185 and 190 nucleotides (*b*), presumably due to minor nibbling at the ends of the 190-base pair DNA/RNA hybrid by S_1 nuclease. RNA was extracted from various adult tissues by homogenization of frozen tissue in 3 M lithium chloride, 6 M urea, 0.5% SDS, 70 mM 2-mercaptoethanol, 10 mM sodium acetate, *p*H 5.0 (ref. 34). After precipitation overnight at 4 °C, the RNA was resuspended in 0.2% SDS, 100 mM sodium acetate, *p*H 5.0, extracted twice with phenol and chloroform and reprecipitated. Single-stranded hybridization probes were prepared using subclones M2 and M3 (see Fig. 1) inserted into the *Sma*I site of M13mp8 (ref. 35). Radioactive probes were excised by digestion with *Eco*RI. For S_1 nuclease protection analysis[36], 2.5 μg of total tissue RNA were hybridized with 100,000 c.p.m. of probe in 20 μl buffer (50% formamide, 1 mM EDTA, 0.4 M NaCl, 10 mM PIPES, *p*H 7.0) at 30 °C (25 °C below T_m for a DNA:DNA hybrid) overnight. Unhybridized material was digested with 100 units of S_1 nuclease (BRL) at 37 °C for 30 min. S_1-resistant DNA was collected by ethanol precipitation and analysed by electrophoresis on 6% acrylamide, 8.3 M urea gels.

Actin gene expression in embryos

In adult frog tissues, sarcomeric and cytoskeletal actin genes show distinct, tissue-specific patterns of regulation. To discover when these differences are first established, we have examined the levels of cytoskeletal, α-cardiac and α-skeletal actin mRNA in RNA extracted from early embryos using RNA blots and S_1 nuclease protection. We detect actin transcripts of three distinct sizes in neurula embryos using a chick β-actin cDNA probe (Fig. 3). To identify each size class and to determine their presence during the course of early development, we have constructed message-specific probes comprising 100–150 nucleotides of the 3′-untranslated sequence from each of the *Xenopus* actin cDNAs (subclones G1, G2 and G3; see Fig. 1). The specificity of each probe was confirmed by genomic Southern blots; each hybridized to a different subset of restriction fragments (data not shown). The three probes were then hybridized individually to nitrocellulose blots of embryonic RNA derived from several stages of early development (Fig. 3).

Our results confirm that *Xenopus* cytoskeletal and α-cardiac actin mRNAs are similar in size to their counterparts in other vertebrates. The cytoskeletal actin transcript of embryos comprises ~2,300 nucleotides whilst the α-cardiac transcript is ~1,600 nucleotides long and co-migrates with its α-skeletal counterpart (data not shown). An intermediate-sized transcript is also detected throughout early development and presumably encodes a further class of cytoskeletal actins. Even in early embryos, the cytoskeletal and muscle-specific actin genes show different patterns of expression. The α-cardiac actin transcripts and their α-skeletal counterparts are absent in the early stages of development, being first detected in neurula embryos. By contrast, a low, constant level of cytoskeletal actin mRNA was detected in all stages before gastrulation. In later stages, the levels of both cytoskeletal and sarcomeric actin mRNAs increase in a similarly dramatic manner.

The time of actin gene activation

Are the actin genes activated specifically during early embryogenesis or do they simply respond to a 'signal' that stimulates embryonic gene transcription in general? We have made careful estimates of the levels of all three actin mRNAs through development and compared their developmental profiles with those of other identified genes. By a quantitative S_1 nuclease protection assay using single-stranded probes radioactively labelled through their entire length, we have obtained a sensitivity 10-fold greater than that provided by RNA blots. We compared the signals derived from each RNA sample with those of a dilution series using tailbud RNA (stage 26), performing each measurement on RNA extracted from individual, staged embryos (see Fig. 4).

Both α-cardiac and α-skeletal actin mRNAs are first detected in stage 14 embryos which have just completed gastrulation, and the two mRNAs increase their subsequent levels in parallel. The observed actin mRNA development profiles diverge from the theoretical curve for a stable gene transcript at this stage, either because of specific activation of the actin genes at the end of gastrulation, or from a similarly timed and equally dramatic change in the kinetics of actin message turnover. From the specific activity of our probes, we believe that a stage 18 (neurula) embryo contains 10^7–10^8 α-cardiac transcripts; this number would be accumulated if the α-cardiac actin gene is single copy and activated in ~5% of cells at stage 13 (activated exclusively in the presumptive somatic mesoderm 1 h before the first transcripts are actually detected). For such a calculation, we assume that stable transcripts are synthesized at a rate of 10

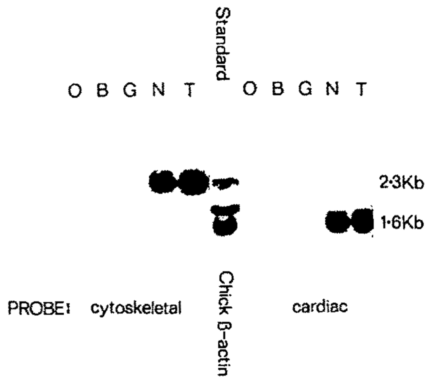

Fig. 3 Actin mRNA accumulation in early embryos. Total RNA was extracted from embryos at successive stages of development as previously described[34], resolved by electrophoresis using formaldehyde-agarose gels[37] and transferred to nitrocellulose[38]. The RNA blots were hybridized individually with mRNA-specific probes (G1 and G2) from the α-cardiac and cytoskeletal actin cDNAs (see Fig. 1 legend). Single-stranded, ^{32}P-labelled probes were synthesized[35] in M13mp8. A further blot containing RNA extracted from a neurula embryo was hybridized with the chick β-actin cDNA probe to serve as a standard that identifies all actin mRNA size classes. The figure is a composite from these experiments, using 10 μg of RNA from fully grown oocytes (O), blastula (B), gastrula (G), neurula (N) and tailbud (T) embryos. Sizes of hybridizing transcripts were estimated by comparison with ribosomal and transfer RNA markers.

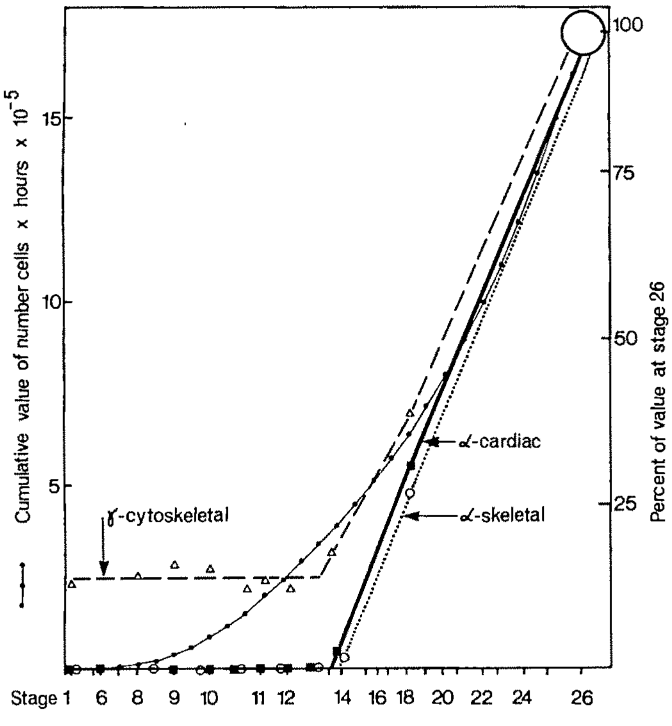

Fig. 4 Temporal changes in actin mRNA content during *Xenopus* development. Relative levels of accumulated actin message were assayed by S_1 nuclease protection as described in Fig. 2 legend, each experiment using the RNA from a single embryo. We confirmed that hydribidization signals increased in a linear fashion with input RNA by including a dilution series of RNA from several embryonic stages. Each point represents the average of several determinations in different experiments. These are plotted as a percentage of the value at stage 26. △- - -△, Cytoskeletal actin mRNA; ■—■, α-cardiac actin mRNA; ○···○, α-skeletal actin mRNA. A theoretical accumulation curve (●—●) (prepared by adding cumulatively the number of nuclei present at each hour of development) has been superimposed for comparison.

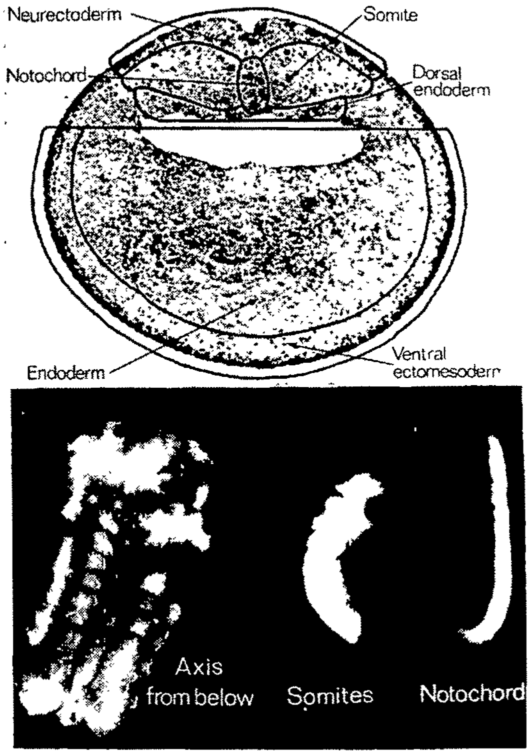

Fig. 5 Dissection of a stage 18 neurula embryo. A transverse section of a stage 18 neurula embryo (1.2 mm diameter) indicating the six fragments that were obtained by dissection, several of which are in the lower figure. After removal of endoderm, ventral ectomesoderm and dorsal endoderm, the remaining fragment (axis) is readily separated into somites, notochord and neurectoderm.

per gene per min[15]. Other genes active in early embryos commence transcription at varying times before muscle actin transcripts are first detected, irrespective of which RNA polymerase is involved[15-18]. Similarly, muscle actin gene activation occurs several hours after the levels of both newly synthesized and accumulated cytoplasmic poly(A)$^+$ RNA begin to increase[19]. We conclude that the sarcomeric actin genes are activated at stage 13, independently of any other gene so far identified.

The relatively constant level of the 2.3-kilobase (kb) cytoskeletal actin mRNA detected in all stages before gastrulation could result from *de novo* gene transcription or the inheritance of maternally derived message (or indeed a combination of both). Certainly by neurula stage, any pool of inherited cytoskeletal transcripts is supplemented by newly synthesized mRNA.

Regional actin gene expression

By the early neurula (stage 14), *Xenopus* embryos show morphological differentiation, possessing endoderm, mesoderm and ectoderm germ layers. The future anterior–posterior axis of the embryo is evident from the polarity of the elevated neural plate, formed by dorsal ectoderm; beneath it lies the notochord (the embryonic 'backbone') which segregates as a mid-dorsal strip from the mesoderm layer. On either side of the notochord, the thickened, dorsal regions of mesoderm largely comprise the precursors of embryonic muscle (the somites)[20]. We dissected neurula embryos (neural folds complete; stage 18) into six different pieces (Fig. 5) and used the RNA from each in the S_1 nuclease protection assay. All the pieces contain cytoskeletal actin mRNA in approximate proportion to their tissue mass (data not shown); α-cardiac and α-skeletal actin mRNA distribution is shown in Fig. 6. Strikingly, the sarcomeric actin transcripts are restricted almost exclusively to the somite region of the mesoderm and are completely absent from an equivalent amount of the adjacent notochord tissue. A minor signal is detected in the ventral ectomesoderm, possibly arising from the

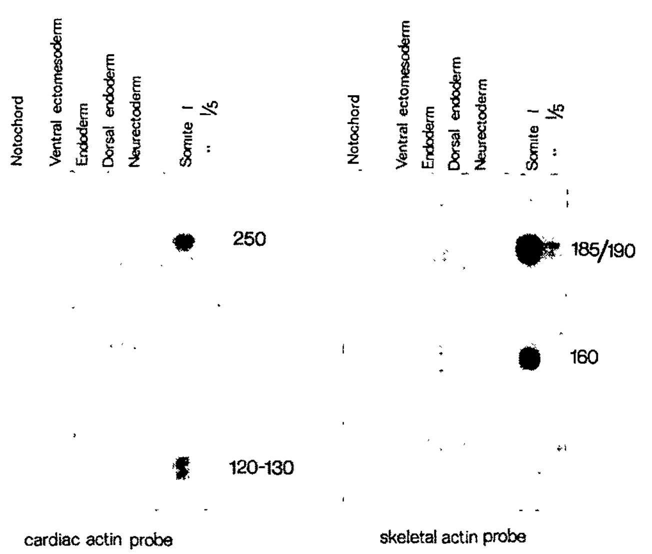

Fig. 6 Region-specific accumulation of muscle actin mRNAs. The six different embryo fragments (Fig. 5) were assayed for the presence of actin mRNAs by the S_1 nuclease protection procedure. α-Cardiac actin mRNA is detected by the presence of protected fragments 250 and 120–130 nucleotides long. α-Skeletal actin mRNA gives a major doublet 185 and 190 nucleotides long (see Fig. 2 legend), and a minor protected fragment about 160 nucleotides in length. This fragment results from partial cleavage of the probe M3 at an A+T-rich region (18 out of 20 bases are A or T). Cleavage in this region is variable, giving a prominent signal in this experiment but a very minor one in others (for example, Fig. 2*b*).

mesodermal component of this fragment which subsequently gives rise to the embryonic heart.

Muscle-gene activation is thus restricted to the mesoderm cell layer in early embryos. Furthermore, within the mesoderm the expression of these genes is precisely regionalized, because the most dorsal portion, the notochord, contains neither α-cardiac nor α-skeletal actin mRNA. We conclude that sarcomeric actin gene activity is restricted to the embryonic tissue from which muscle cells are later derived. Muscle actin mRNA accumulation commences very early in development, several hours before the morphological differentiation of muscle tissue. Developmental regulation of actin genes has also been studied in fruitflies[21,22] and sea urchins[23–25]. Several actin mRNAs are synthesized in these organisms, each with a distinct developmental profile. However, in contrast to amphibians, the appearance of muscle actin gene transcripts is a later embryonic event, coinciding with the formation of muscle-containing tissues in larval or metamorphosis stages.

Myogenesis and actin gene expression

The dorsal, flanking region of the mesoderm is irreversibly committed to embryonic muscle formation in the stage 10 gastrula *Xenopus* embryo[26], several hours before newly synthesized muscle proteins are first detected[7]. This may be a common feature of amphibian embryogenesis (see ref. 27). Our present results also show that mesoderm commitment occurs significantly before actin gene transcription and no major store of untranslated muscle actin transcripts is accumulated before α-actin protein is first synthesized in *Xenopus* embryos.

Muscle precursors, the embryonic somites, begin to appear a few hours after sarcomeric actin gene activation[5]. From stage 14 (actin gene activation) to stage 26 (tailbud embryo; 16 somites) the level of muscle actin mRNA increases over 20-fold, yet the total number of the cells in the embryo only doubles. Both somitic mesoderm and subsequent somite cells must therefore accumulate muscle actin transcripts over this period.

During the same interval, more lateral regions of mesoderm extend ventrally, eventually fusing along the midline to form the embryonic heart rudiment, thus being derived from a quite distinct region of the gastrula mesoderm from the somites. Somitic mesoderm accumulates similar amounts of both α-cardiac and α-skeletal muscle actin mRNA whilst immediately adjacent mesoderm cells and their derivatives (such as notochord) do not. This suggests that the initial events that regulate the actin multi-gene family distinguish muscle actin-encoding genes from their more distantly related cytoskeletal-type counterparts, whilst subsequent controls establish the final tissue specificity of the various muscle actin genes. Vertebrates seem to differ in the extent to which individual sarcomeric actin genes are expressed in each adult, muscle-containing tissue. The predominant muscle actin mRNA in adult mouse heart tissue (the α-cardiac form) provides about one-third of all the sarcomeric actin transcripts in fetal skeletal muscle[28]. This is replaced by α-skeletal actin mRNA in the skeletal muscle of newborn and adult mice. In neonatal rats, both α-cardiac and α-skeletal actin gene transcripts are present in heart tissue[29]. In man, both adult heart and skeletal muscle contain a significant proportion of each kind of sarcomeric actin message[30]. The initial activation of actin genes in early embryos from these species has not been documented.

Co-expression of α-cardiac and α-skeletal actin genes is not a transient phenomenon in early amphibian development, as we have detected roughly equivalent levels of each transcript in embryonic heart, somites and the myotomes of swimming tadpoles (stage 42) 3 days after fertilization (data not shown). It seems highly improbable that only one set of transcripts is utilized in each of these tissues and more likely that each functional embryonic organ uses both types of muscle actin protein in their contractile apparatus. If so, this raises an intriguing problem: why do adult muscle tissues express the sarcomeric actin genes in a tissue-specific manner if such complex regulation is unnecessary in larval stages?

Conclusions

The α-actin genes are the first identified genes known to be activated in a tissue-specific manner in the early amphibian embryo. Transcription of these genes is regulated in a cell type-specific manner, being restricted exclusively to those regions of the mesoderm that are committed to form embryonic muscle. The presence of muscle actin transcripts therefore offers a convenient molecular marker for these cells and their detection provides the basis of an assay for cytoplasmic factors involved in early cell determination[31].

Resolution of synthetic *att*-site Holliday structures by the integrase protein of bacteriophage λ

Pei Ling Hsu* & **Arthur Landy**

Division of Biology and Medicine, Brown University, Providence, Rhode Island 02912, USA

Site-specific recombination of the bacteriophage λ genome into and out of the host bacterial genome is postulated to involve the formation of Holliday structure intermediates by reciprocal single-strand exchanges. Synthetic analogues of the predicted recombination intermediates are resolved in vitro *by the protein product of the λ* int *gene. Some of the structural features and reaction conditions for this genetic recombination can now be defined.*

INTEGRATION of the bacteriophage λ chromosome into a bacterial chromosome occurs by a reciprocal site-specific recombination between the phage *att*P site and the bacterial *att*B site. The resulting prophage *att* sites, *att*L and *att*R, are themselves able to recombine to regenerate *att*P and *att*B during excision of the viral genome (see refs 1, 2 for reviews). Both integrative and excisive recombination require the phage-encoded protein Int and the host-encoded protein IHF (integration host factor)[3,4]. Additionally, efficient excision requires the phage-encoded protein Xis[5,6]. Although purified Int protein is a type I topoisomerase that nicks and reseals pBR322 supercoiled DNA one strand at a time[3], no activity other than specific DNA binding has been found for purified IHF[1,4].

The *att*P site has 240 base pairs (bp)[7]; it contains a 15 bp 'common core' sequence (occurring in all four *att* sites)[8], three binding sites for IHF[1] and two classes of Int binding sites[9,10]. Essential DNA sequences to the left or right of the central 'core region' comprise the P arm and P′ arm respectively. (Similarly, in *att*B the essential left and right sequences are labelled B and B′ respectively.) The *att*B site is much smaller, extending approximately 5 bp to either side of the 15 bp common core[11]; it does not have any IHF recognition or arm-type Int binding sites. *att*B and *att*P do, however, have a similar junction-type Int binding site at each core-arm junction[10].

Int-dependent recombination does not involve any degradation or synthesis of DNA nor does it require any high-energy cofactors[4]. During recombination, the DNA strands are cut within the common core at position −3/−2 (from the centre of the core) in the 'top' strand and at position +4/+5 in the 'bottom' strand, to generate a 3′-protruding 7 bp stagger or overlap region[12], (referred to as O in POP′ and BOB′). Within the overlap region, DNA: DNA homology between the *att* sites is necessary for efficient recombination[13]. Genetic evidence suggests that at least some fraction of Int-dependent recombinants proceed via a single-strand exchange intermediate or Holliday structure[14,15].

Holliday structures, also referred to as χ-forms, are formed by the reciprocal exchange of single strands between two DNA duplexes[16-18]. They are thought to be intermediates in several recombination pathways, and would be resolved to recombinant products by a second cycle of nicking and re-ligating[19,20]. χ-

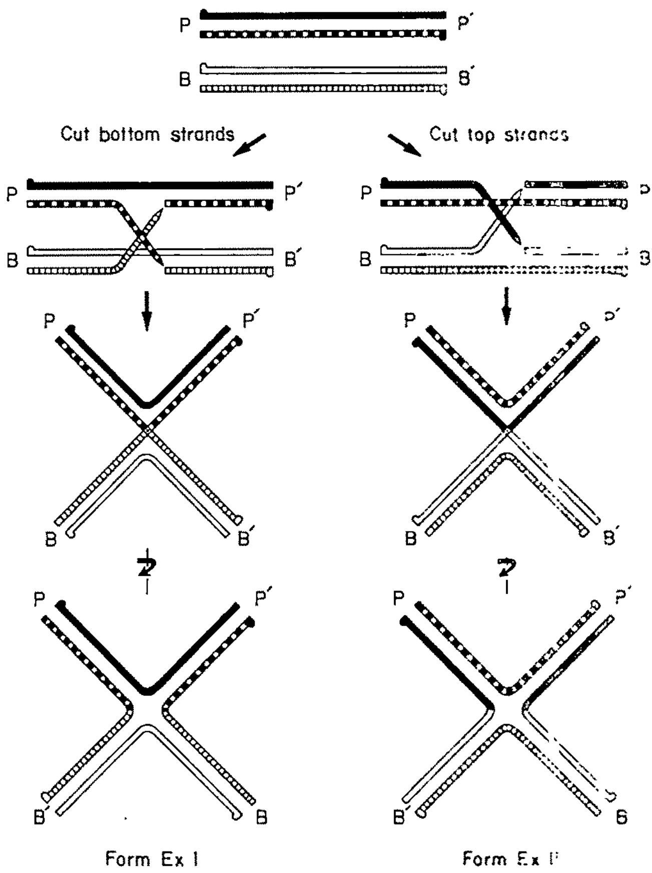

Fig. 1 Formation of Holliday structures (χ-forms) during λ site-specific recombination. The *att*P top (▬) and bottom (▨) strands and the *att*B top (▭) and bottom (⬚) strands have their 5′ termini indicated by a knob. The cutting and exchange of two bottom strands (left) results in form ExI, whereas the cutting and exchange of two top strands (right) results in form ExII. In the case where *att*L and *att*R are the parental DNAs (not shown here), the cutting and exchange of the two top strands would result in form ExI and the cutting and exchange of the two bottom strands would result in form ExII.

---

* Present address: Department of Pathology, University of Texas Health Science Center, Houston, Texas 77225, USA.

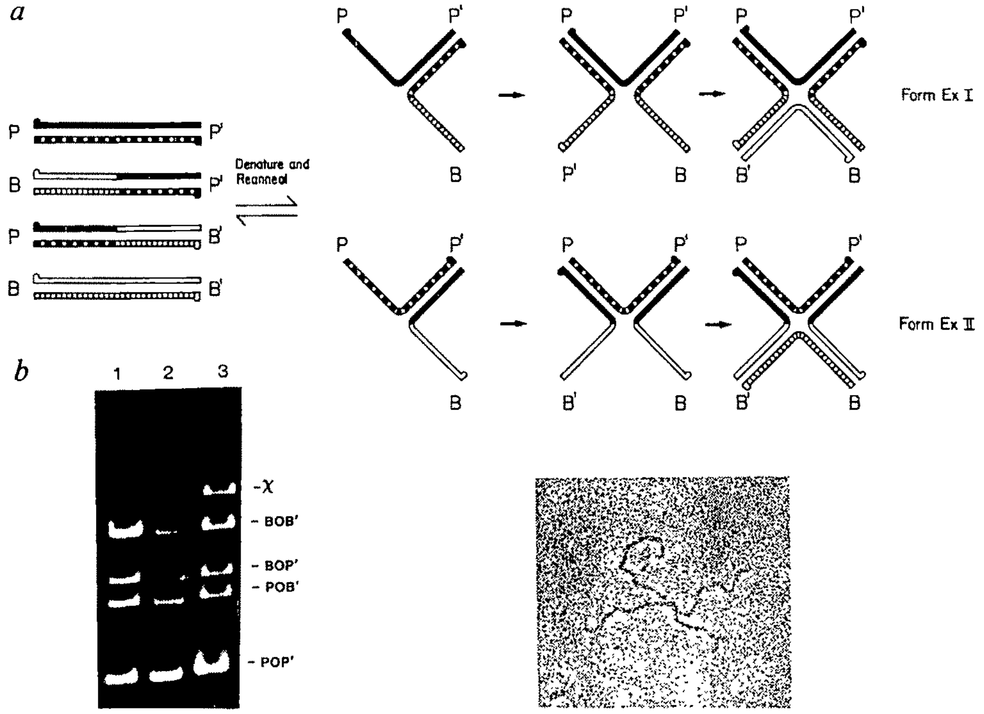

Fig. 2 Construction of forms ExI and ExII Holliday structures with a branch point in the common core region of the *att* site. Equivalent amounts of the four parental fragments, containing the POP', BOP', POB' and BOB' DNA sequences, were denatured and reannealed as described here. *a*, Schematic illustration of the stepwise formation of χ-structures during the reannealing process. Designations for the *att*P top (▬) and bottom (▪▪▪) strands and the *att*B top (▭) and bottom (▤) strands are also used to indicate the corresponding DNA strands in the prophage *att* sites BOP' and POB'. The 5' termini are marked with a knob. *b*, The ethidium bromide-stained agarose gel shows the four DNA restriction fragments before (lane 1) and after (lane 2) denaturation and after reannealing (lane 3). Electron micrograph shows DNA eluted from the gel band marked χ-form.

Methods: 40–120 pmol of restriction fragments in 0.8–1.0 ml were denatured and reannealed by one of the following two procedures: (1), the DNAs were denatured by boiling at 100 °C for 2 min in 1 mM Tris-HCl (*p*H 7.9), 0.1 mM EDTA, followed by rapid chilling in ice water. One-tenth volume of 20 × SSC (3 M NaCl, 0.3 M Na citrate) was added and the mixture was placed in a 65 °C water bath that was then allowed to equilibrate to room temperature overnight. (2), DNA restriction fragments in low melting agarose were heated at 68 °C until the agarose was melted and then placed at 37 °C. They were then denatured in 0.1 M NaOH for 5 min; after adding 1/2 vol of deionized formamide and neutralizing with acetic acid, they were incubated at 37 °C overnight. The χ-forms were purified by gel electrophoresis in 1% agarose at 1.8 V cm^{-1} in E* buffer (18 mM NaCl, 2 mM EDTA, 40 mM Tris, 20 mM sodium acetate, adjusted to *p*H 8.0 with acetic acid). DNA was electroeluted from the excised gel band and purified by elution from a BND cellulose column as described previously[42].

forms have been observed in *Escherichia coli* with phage[21–24] and plasmid DNAs[25], in yeast with 2 μ circle DNA[26] and in HeLa cells with adenovirus DNA[27]. In the Int-dependent pathway of λ it has not yet been possible to detect χ-form recombination intermediates. We report here an investigation of this aspect of the recombination reaction by construction of 'synthetic' Holliday structures that are structurally analogous to a reciprocal single-strand exchange intermediate in site-specific recombination.

Generation of Holliday structures

In forming Holliday structures (Fig. 1), the two DNA helices are first aligned with respect to their common core sequences. The cutting and reciprocal exchange of the two 'bottom' strands results in form ExI, and of the 'top' strands, form ExII. (We identify the individual DNA strands in each helix as either 'top' or 'bottom' in accordance with the convention of writing the four *att* sites as POP', BOB', POB' and BOP'; see Fig. 1.) In site-specific recombination, forms ExI and ExII are not conformational isomers—they cannot be interconverted without breakage and resealing of the DNA strands. This contrasts with Holliday structures generated in homologous recombination, where forms ExI and ExII are indistinguishable because both partners have the same DNA sequence.

We constructed 'artificial' Holliday structures (that is, without recombination) from four restriction fragments containing the POP', BOB', BOP' and POB' DNA sequences. A mixture of the four restriction fragments was denatured and reannealed in a manner analogous to that first used by Bell and Byers[26]. During renaturation, some of the single strands anneal with their original complement to regenerate the original restriction fragment. Alternatively, annealing between two strands originating from different restriction fragments (such as POP' and POB') generates a 'Y' structure comprising one duplex arm (such as P) and two single-stranded tails (such as P' and B'). Each of the single-stranded tails can further anneal with complementary sequences originating from a different restriction fragment, and this leads by analogous steps to formation of the four-armed Holliday structure (Fig. 2*a*).

Forms ExI and ExII comprise two different sets of DNA strands; from each restriction fragment one DNA strand is found only in ExI, for example, the top strand of POP', and the other strand is found only in ExII, for example, the bottom strand of POP' (see Fig. 2*a*). Thus, by starting with a POP' restriction fragment containing ^{32}P in only the top strand or the bottom strand, it is possible to label specifically either ExI or ExII respectively. In an alternative procedure it is possible to start with the isolated strands of each restriction fragment; then the appropriate combination of four (out of the total of eight) can be annealed to generate either ExI or ExII.

The χ-structure has a higher molecular weight than any of the other DNAs in the annealing mixture and is readily purified by agarose gel electrophoresis on the basis of its unique mobility (Fig. 2*b*). To prove that the unique slow-migrating band is indeed χ-form DNA, we eluted it from the gel and examined it in the electron microscope. At least 90% of the DNA has the expected χ-structure and arm lengths (see Fig. 2*c*). Furthermore, if eluted DNA was subjected to a second cycle of denaturation and renaturation, the four initial restriction fragments were recovered as expected. Finally, in the resolution experiments described below we were able to convert 100% of the χ-form DNA preparation into those linear products expected from cutting at the branch points of a simple χ-form structure.

Resolution of Holliday structures

A critical test of whether the synthetic χ-structures do correspond to intermediates of site-specific recombination is the ability of Int protein to resolve them to the expected linear products. Theoretically a synthetic *att* site Holliday structure might be resolved in either the integrative mode, generating *att*L

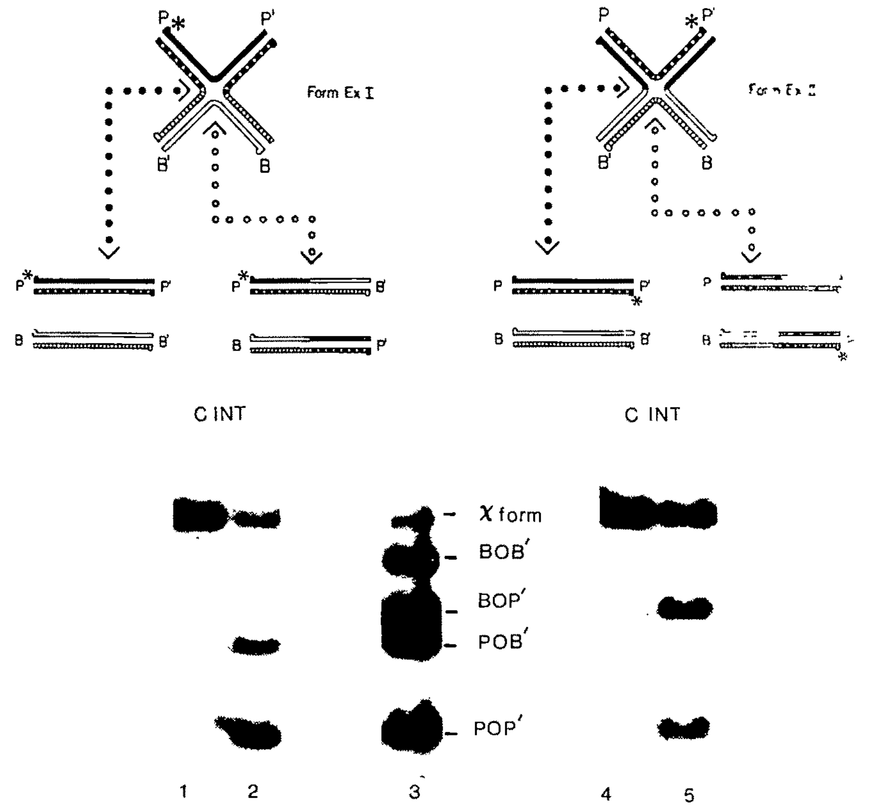

Fig. 3 Resolution of forms ExI and ExII by Int protein. The strands of the four *att* sites and the 5′ termini are designated as in Fig. 2. The positions of the unique ^{32}P label (*) in each χ-form that are expected after resolution are shown in the schematic diagram (see text). Lane 3 shows the positions of the χ-forms and the four restriction fragments used to make the χ-forms. Each labelled χ-form was incubated without (C) or with (INT) Int protein. Radioactive bands were visualized by autoradiography.

Methods: χ-Forms were constructed according to the first procedure described in Fig. 2 legend using the POP′ *Hin*dIII-*Bam*HI-492 fragment of pWR1, the BOB′ *Eco*RI-*Bam*HI-1740 fragment of pWR101, the BOP′ *Eco*RI-*Bam*HI-1210 fragment of pPH201 and the POB′ *Hin*dIII-*Bam*HI-1020 fragment of pPH202 (Table 1). The POP′ restriction fragment was labelled before denaturation with [γ-^{32}P]ATP and polynucleotide kinase at the *Hin*dIII site (for labelling form ExI) or at the *Bam*HI site (for labelling form ExII). Each reaction mixture (20 µl) contained 0.1 µg of ^{32}P-labelled form ExI or form ExII in 50 mM Tris-HCl (*p*H 7.9), 5 mM EDTA, 50 mM KCl and 6.25 mM spermidine. Incubation with 1 U of Int protein (purified by N. Hasan) was carried out at 25 °C for 60 min. (In these reaction conditions 1 U of Int plus 1 U of purified IHF[4,43] gives optimal recombination of 0.1 pmol supercoiled *att*P, pWR1, and 0.1 pmol of linear *att*B, pWR101.) The reactions were terminated with SDS (0.1% final) and electrophoresed on a 1% agarose gel as described for Fig. 2.

and *att*R (vertical cuts in ExI and ExII, Fig. 3) or in the excisive mode, generating *att*P and *att*B (horizontal cuts in ExI and ExII, Fig. 3). This resolution reaction is presumably equivalent to the second half of normal integrative or excisive recombination. In fact, in reaction conditions suitable for *in vitro* recombination, purified Int protein efficiently resolves both forms ExI and ExII into the expected linear products (Fig. 3).

Each χ-form is labelled with only one ^{32}P atom and, therefore, in each pair of products, only one will be radioactively labelled. Under these experimental conditions the resolution of form ExI yields approximately three times more *att*P than *att*R product, thus indicating a preference for the 'excisive mode' (cutting the bottom strands). On the other hand, resolution of form ExII yields approximately twice as much *att*L as *att*P product, thus indicating a preference for the 'integrative mode' (cutting the bottom strands). This is a good example of how an overall preference for cutting the bottom strand has opposite consequences for ExI (generating excision-type products) and ExII (generating integration-type products). The patterns and degree of preferential strand-cutting are significantly influenced by several experimental parameters (currently under investigation); this is a particularly interesting aspect of the reaction because of its relevance to directionality in site-specific recombination.

Following resolution, there is an additional band on alkaline denaturing gels, corresponding to full-length *att*R for ExI, and full-length *att*L for ExII (data not shown). This transfer of label from a POP′ strand to the corresponding strand of a prophage *att* site indicates the successful ligation of DNA strands during resolution.

Specificity and factors

The strand exchange in λ site-specific recombination resembles the relaxation of superhelical DNA by certain topoisomerases (including the type I topoisomerase activity of Int protein) in

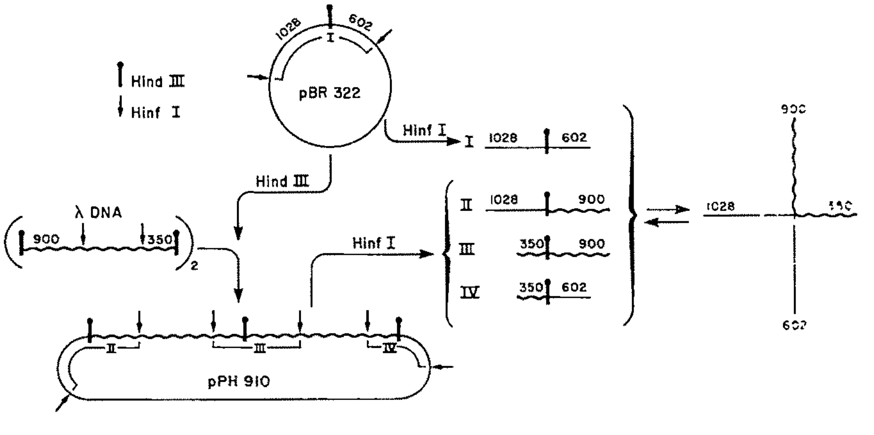

Fig. 4 Construction of a non-*att* Holliday structure. The *Hin*dIII fragment of λ DNA (〰〰), which extends from 57.0% to 52.4% on the λ map and does not contain an *att* site, was cloned as a tandem duplication into the *Hin*dIII site of pBR322 (———), to generate plasmid pPH910. Three *Hin*fI fragments of pPH910 were isolated for the χ-form construction: fragment II consists of the left pBR322-λ junction, fragment III of the head-to-tail junction of the two λ fragments, and fragment IV of the right λ-pBR322 junction. Fragment I is the pBR322 *Hin*fI fragment into which the λ DNA had been inserted. For each fragment, and for each arm of the χ-structure, the amount (base pairs) of pBR322 DNA or λ DNA is indicated.

Methods: The χ-form was generated by alkali denaturation and renaturation according to scheme (2) and purified by agarose gel electrophoresis as described in Fig. 2 legend.

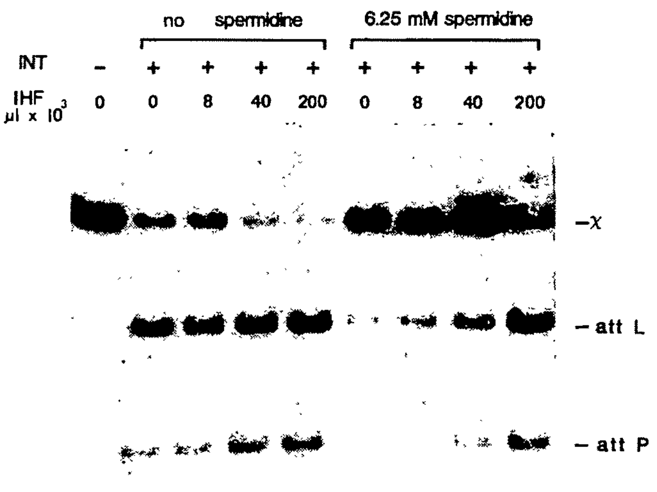

Fig. 5 Effect of IHF protein and spermidine on resolution. ^{32}P-labelled form ExII was constructed and isolated as described in Fig. 3 legend. The composition and processing of each resolution reaction was the same as described for Fig. 3 except that incubation with 0.2 U of purified Int protein was for 30 min. Purified IHF protein[4] (a gift from H. Nash) at 1 U μl^{-1} and spermidine were present as indicated.

that the DNA strands are broken and resealed in the absence of DNA synthesis and energy cofactors (see refs 28, 29 for reviews). This raises two points of interest: as the topoisomerase I activity of Int works efficiently with a substrate such as supercoiled pBR322 DNA[3], can it resolve a Holliday structure that does not contain an *att* site? Similarly, is the Holliday structure resolved by other DNA topoisomerases?

To address these questions, we constructed a Holliday structure that bears no *att* site DNA sequences (Fig. 4). This structure is not resolved into linear products by Int protein, either in conditions for *in vitro* recombination or conditions for the nicking-closing reaction. The addition of host factor also has no effect. We also tested the ability of three different topoisomerases to resolve the *att* site Holliday structure (these enzymes were a gift from Leroy Liu), HeLa cell topoisomerase I[29], T4 topoisomerase II[30,31] and calf thymus topoisomerase II, whose purification and properties (L. F. Liu, unpublished results) are identical to HeLa topoisomerase II[32]. In conditions where these enzymes relaxed approximately 30–70% of supercoiled DNA, we observed no resolution of Holliday structure (data not shown). We conclude that, in these experimental conditions, the ability of Int protein to resolve a Holliday structure is specific for the *att* site DNA sequences and is not merely a general property of DNA topoisomerases.

In an *in vitro* reaction, the integrative and excisive recombination functions of Int require the *E. coli*-encoded IHF protein and are strongly stimulated by the presence of spermidine. In contrast, the topoisomerase activity of Int does not require IHF protein and is inhibited by the addition of spermidine[3]. Int resolution of the Holliday structures is also independent of IHF

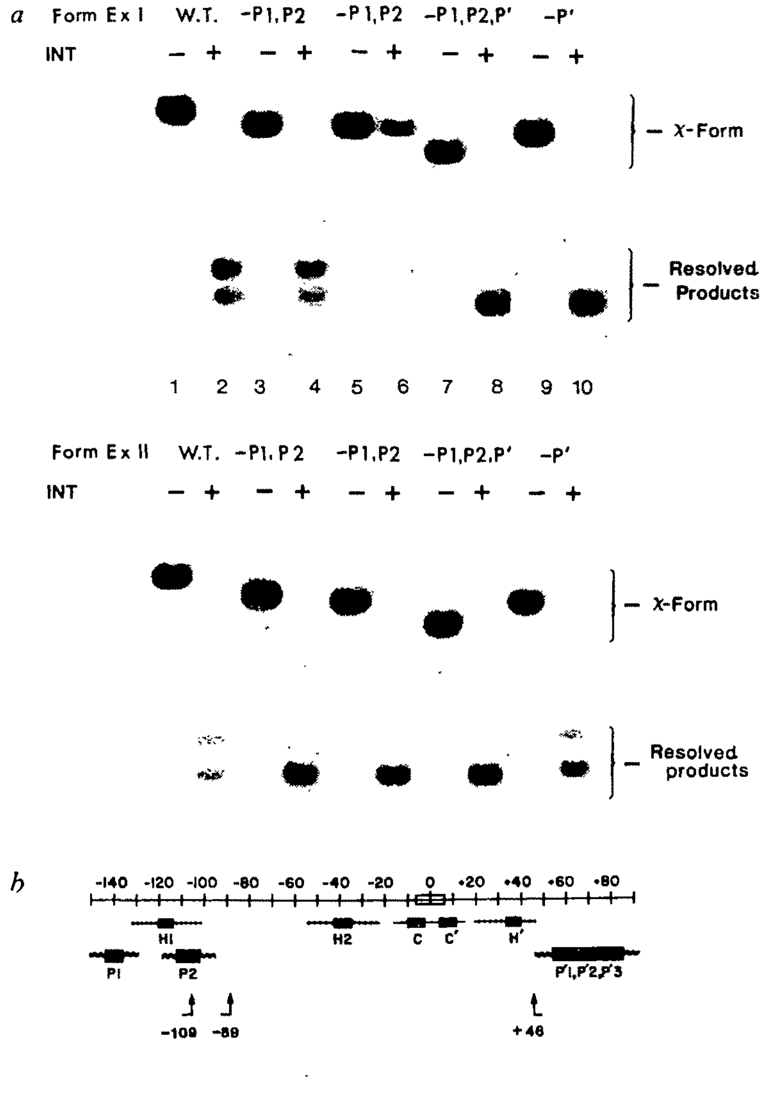

Fig. 6 Int resolution of χ-forms lacking one or more arm-type Int binding sites. χ-forms composed of intact *att* sites (W.T.) or lacking the indicated arm-type Int binding site(s) ($-$P1, P2, etc.) were constructed from the appropriate *Hin*cII restriction fragments (Table 1, using the second procedure in Fig. 2). *b*, The *att*P coordinates for the 15 bp common core (⊟); the consensus recognition sequences (—■—) and the approximate region of DNA covered (as determined by nuclease protection) for each of the following: the junction-type Int binding sites, C and C' (—■—■—), the arm-type Int binding sites P1, P2, P'1, P'2, and P'3 (—■—)[9,10], the IHF binding sites H1, H2 and H' (‖■‖)[1]. The endpoints of *att* DNA in the three deletions used to construct the different χ-structures are indicated ($-$109, $-$89 and +46) (see Table 1). Each χ-form was incubated in the absence ($-$) or presence (+) of purified Int protein in a 20-μl reaction that contained ~0.01 μg of χ-form, 0.5 μg of supercoiled pBR322 DNA and 1 U of purified Int. After electrophoresis of the reaction products, gels were stained with ethidium bromide (0.5 μg ml^{-1}) to visualize the nicking-closing activity of Int on the supercoiled pBR322 DNA. The expected levels of activity were observed in each case (data not shown). The ^{32}P-labelled χ-forms and resolution products were visualized by autoradiography. The size (in base pairs) of each labelled resolution product is as follows: BB', 940; BP', 1,077; BΔ', 886; PB', 1,114; ΔB', 972 (lane 4) and 952 (lanes 6 and 8). In this exposure of the autoradiogram, resolution products of similar size are not clearly resolved in several of the lanes; shorter exposures (and other gels) show that both resolution products are obtained in each reaction. The incomplete resolution observed in lane 6 of the upper gel is not typical; in other experiments in these conditions resolution is complete.

Methods: Reaction conditions, processing and gel electrophoresis were as for Fig. 3, with no spermidine. For ^{32}P labelling of forms ExI and ExII, the BOB' *Hin*cII fragment was first labelled at the 5' termini with polynucleotide kinase and then strand-separated by gel electrophoresis. The top strand of BOB' was incorporated into form ExI and the bottom strand into form ExII (see Fig. 2) by annealing with the other three restriction fragments (Table 1). The specific activity is the same for the entire form ExI family (or the entire form ExII family), because the ^{32}P label is always on the BOB' strand which is common to all five χ-forms (see Table 1).

protein (Fig. 3), resolving 95–100% of the Holliday structure to linear products in the absence of IHF. Int purified from the *him*A deletion mutant K5242 (ref. 33 and H. Miller, in preparation) is also efficient in resolution (data not shown). However, when limiting amounts of Int are used, IHF does stimulate resolution in a dose-dependent manner (Fig. 5). Spermidine inhibits resolution; omission of spermidine results in a three- to fivefold enhancement (Fig. 5). Thus, as might be expected, the requirements for the overall recombination reaction are greater than the requirements for the resolution phase.

Structural requirements

We have shown that the arm-type Int binding sites are essential for integrative recombination. The role of these sites, which are quite distant from the cross-over locus, is unclear (see Fig. 6, bottom)[7,9]. Are they required throughout the reaction or only involved in some phases? If the latter, are they required for synapsis between the recombining partners and possibly the initial strand exchange, or are they required for resolution of the recombinational intermediate? To address these questions, we have constructed Holliday structures lacking the P arm and/or P′ arm Int binding sites and asked which, if any, of these is an acceptable substrate in the resolution reaction.

Holliday structures containing various deletions of the P and/or P′ arms were constructed by annealing a ^{32}P-labelled separated strand of BOB′ with different combinations of the appropriate restriction fragments. Two families of χ-forms were constructed, representing forms ExI and ExII for each deletion analysed (Table 1). The restriction fragments and constructions were designed so that all of the arms in every χ-structure are perfect duplexes over their entire length.

In any one series of experiments (see Fig. 6), all of the χ-forms have the same specific activity. This is because the single ^{32}P atom in each χ-structure is donated by the same BOB′ restriction fragment which has been end-labelled and strand-separated before being distributed into the respective annealing mixtures. This protocol facilitates the comparison of resolution efficiencies under identical Int:DNA ratios. As an additional (internal) control, supercoiled pBR322 DNA was added to each reaction mixture to monitor the topoisomerase activity of Int.

In a 1-h incubation with χ-form, pBR322 supercoiled DNA and Int (present in a molar ratio of 1:20:30), approximately 70% of the supercoiled molecules are relaxed in all of the reaction mixtures. Concomitantly, Int protein resolves all of the Holliday structures with 95–100% efficiency, irrespective of the presence or absence of the arm-type Int binding sites (Fig. 6). For all Holliday structures in this form ExI family, resolution occurs in both the integrative and excisive modes. Similar results and efficiencies are obtained with the analogous family of form ExII Holliday structures. When the concentration of Int is lowered (χ-form:pBR322:Int at 1:20:10) so that χ-form resolution is reduced to ~30%, the resolution efficiency of Holliday structures with each of the deletions is still the same as the non-deleted form (data not shown). We conclude that the arm-type Int binding sites that are required for integrative recombination are dispensable for the resolution of Holliday structures resembling the cross-over region of recombining *att* sites.

Discussion

Does Int-dependent site-specific recombination proceed by a concerted mechanism in which both DNA strands on each partner are cut at the same time and then exchanged and re-ligated, or does it proceed in two distinct steps where first, only one strand on each partner is exchanged to generate a Holliday structure, and second, the single-strand exchange intermediate is resolved by a second cycle of nicking and re-ligation?

We have shown here that Holliday structures with their branch points in the common core region of the *att* site are efficiently

Table 1 Construction of different χ-form structures

χ-Forms Intact	Arm sites deleted −P1 −P2	 −P1 −P2	 −P′	 −P1 −P2 −P′	Plasmid	*att*	P arm or Δ arm	P′ arm or Δ′ arm	B arm	B′ arm
+					pWR1	PP′	−251(734)	+242(517)		
	+				pPH55	ΔP′	−109(592)	+242(517)		
		+			pPH56	ΔP′	−89(572)	+242(517)		
			+		pPH310	PΔ′	−251(734)	+46(326)		
				+	pPH5610	ΔΔ′	−89(572)	+46(326)		
+	+	+			pPH201	BP′		+242(517)	−560

	+				pPH551	ΔB′	−109(592)			+380
		+		+	pPH561	ΔB′	−89(572)			+380
+	+	+	+	+	pWR101	BB′			−560	+380

χ-Forms with intact *att* sites or lacking one or more of the arm-type Int binding sites (as labelled), were constructed using the indicated (+) restriction fragments, one from each of the four classes (see Fig. 6). For example, to make a Holliday structure lacking the P1 and P2 sites, an isolated BOB′ strand from pWR101 was annealed with the ΔOB′-containing fragment of pPH551, the BOP′-containing fragment of pPH201 and the ΔOP′-containing fragment of pPH55. The plasmids from which the *att* site restriction fragments (*Hin*cII) are isolated are shown. The construction att sites (pWR1, pWR101, pPH201 and pPH202), or *att*P with distal deletions of the P and P′ arms (pPH55, pPH56, pPH310), has been described previously[7]. Transfer of the *att*P deletions to the other *att* sites was as follows: Int-dependent *in vitro* recombination was carried out (with an extract containing Xis) on head-to-tail heterodimer plasmids containing ΔOP′ and POB′; to make pPH551, the dimer consisted of pPH55 and pPH202, to make pPH561, the dimer consisted of pPH56 and pPH202. After recombination the DNA was digested with *Eco*RI, circularized and transformed into HB101. Plasmids containing the recombinant ΔOB′ site were identified by their restriction digestion patterns. For plasmids pPH110 (BOΔ′) and pPH5610 (ΔOΔ′) the Δ′ arm is the *Dde*-*Bam*HI fragment from pPH310. It was ligated through the *Dde* site in the core to the appropriate *Eco*RI-*Dde* fragment, from pPH201 for the B arm or from pPH56 for the Δ arm. The four *att* site arms are denoted P, P′, B and B′ as described in the text; any change (deletion) in one of the phage *att* site arms is denoted as Δ (corresponding to P) or Δ′ (corresponding to P′). The extent of phage *att* site sequence is indicated in base pairs from the centre of the core extending left (−) or right (+) (using the conventions of ref. 8) (see Fig. 6). The *Hin*cII restriction fragments chosen for these constructions also contain neighbouring pBR322 DNA, thus making it possible to generate physically longer (fully duplex) arms in the final χ-structure; numbers in parentheses indicate the total amount of DNA (phage DNA plus pBR322 DNA) in that arm of the χ-form. DNA from the region around the bacterial *att* site is indicated in base pairs (approximate) from the centre of the core extending left (−) or right (+)[8]; these numbers also indicate the total amount of DNA in that arm of the χ-form (that is, these arms do not have pBR322 sequences).

resolved by purified Int protein. In a mixed recombination reaction containing both χ-form (0.01 pmol) and *att*P and *att*B (0.1 pmol each), 1 U of Int and IHF give ~30% recombination between the *att* sites and ~90% resolution of the χ-form (data not shown). It seems highly unlikely that this unique substrate would be utilized in such a specific and efficient manner if it were not part of the normal recombination pathway. We infer that Int-dependent recombination most probably proceeds through a single-strand exchange Holliday intermediate. Resolution of this intermediate is probably very closely coupled with its formation, as suggested by the efficiency of χ-form resolution, the low frequency of branch migration observed in *in vivo* crosses[14,15] and the failure to find such forms accumulating during recombination. A mechanism that exchanges DNA strands one pair at a time is compatible with the type I topoisomerase activity of Int, and with the four-stranded DNA structure that has been proposed for synapsis[3,34].

The finding that purified Int protein efficiently resolves the Holliday intermediate in the absence of IHF (or Xis) substantiates its role in executing the cutting and ligating reactions of recombination[3,4,12,35]. Because IHF does not participate directly in the strand exchange reaction (resolution), its obligatory participation in integrative recombination is probably due to a role in the formation of Int-*att* complexes or in the synapsis of two *att* sites.

A striking feature of the Int resolution reaction is its specificity for *att* site DNA—in particular for the Int recognition sites at the core-arm junctions. Holliday structures lacking *att* site sequences are not resolved by Int. Of the known enzymes, only the T4-encoded endonuclease VII has also been shown to nick specifically at the branch points of χ-structures[36]. In contrast to the Int reaction, however, endonuclease VII is not sequence specific and does not appear to reseal the nicked DNA without the aid of DNA ligase.

We have shown here that resolution is efficient even with a Holliday structure lacking all the Int binding sites in the P and P′ arms and containing only the four Int binding sites at the core-arm junctions (Fig. 6). Because a Holliday structure lacking the junction-type sites is not resolved by Int (Fig. 4), we conclude that this family of Int recognition sites (C, C′, B and B′) is both necessary and sufficient for cutting and re-ligating DNA. The corollary of this conclusion is that the Int binding sites in the arms, although required for *att*P recombination, are not required for the cutting and re-ligation reaction. This is consistent with the finding that a single core-type Int binding sequence, even in non-*att* DNA, is sufficient for nicking by Int protein (ref. 35 and W. Ross and A.L., unpublished results). We infer that the Int sites in the arms function in synapsis of the recombining sites and/or formation of a presynaptic multimeric complex involving *att*P and the necessary proteins. In this context it is interesting that higher order complexes involving *att*P and approximately 10 Int monomers have been observed in the electron microscope[37,38] and nuclease digestion patterns[7,9,39] and topological transformations during recombination[40,41] suggest a wrapping of DNA around, or along the surface of, Int protein(s).

We have shown here that both forms ExI and ExII can be resolved in the integrative mode (producing *att*L and *att*R) or in the excisive mode (producing *att*P and *att*B). This suggests that in these experimental conditions either form ExI or form ExII could serve as an intermediate of either integrative or excisive recombination. Furthermore, as resolution can occur by cutting either pair of strands, there is the possibility that some attempts at recombination are abortive: if the same pair of strands is used for both the first and second cross-over, the original parents are restored. Thus, the overall efficiency of recombination between any two *att* sites could be determined not only by the formation of Holliday intermediates but also by the directionality of their resolution. In our experiments the relative efficiency of resolution was not the same in both directions, with either form ExI or form ExII. It will be interesting to determine how this directionality is influenced by reaction conditions and the various components of the recombination reaction.

We thank Noaman Hasan for purified Int protein, Howard Nash for purified IHF protein, Leroy Liu for the topoisomerases, David Straney for the electron microscopy and Breck Beyers for helpful advice. Lina Vargas and Shirley Rodrigues provided technical assistance. This work was supported by NIH grant AI13544.

Preferential utilization of the most J_H-proximal V_H gene segments in pre-B-cell lines

The most J_H*-proximal* V_H *gene segments are used highly preferentially to form* V_HDJ_H *rearrangements in pre-B-cell lines. This result demonstrates that the rate at which immunoglobulin* V_H *gene segments recombine is influenced by their chromosomal organization, and that the initial repertoire of* V_H *genes expressed in pre-B cells is strikingly different from that seen in mature populations.*

THE genetic information encoding the murine immunoglobulin heavy chain variable (V) region is formed from the juxtaposition of members of three separate clusters of germ-line DNA elements: variable segments (V_H), diversity segments (D) and joining segments (J_H)[1,2]. Approximately 15 D segments are situated 1 to 80 kilobases (kb) upstream from a 2-kb region containing the four J_H segments[3-5], while the 100-200 V_H segments lie at an unknown distance 5′ to the D segments[6,7]. A complete V_HDJ_H variable region gene is assembled during the pre-B-cell stage of the murine B-lymphocyte differentiation pathway via an ordered two-step process: D to J_H joins occur first and on both chromosomes, followed by V_H to DJ_H rearrangement[6]. The tremendous diversity of antibody specificities is due, in part, to the large repertoire of V_H gene segments which are apparently randomly represented in the mature antibody population[8]. The murine V_H gene segments can be divided into approximately ten families based on nucleotide sequence homology; the members of each family are grouped together on the chromosome[9-12]. The relative locations of these families on chromosome 12 have recently been mapped[13]. Little is known about the developmental control of the rearrangement, and subsequent expression, of the many V_H regions. If the choice of V_H gene segments used in rearrangements were not random, it could be mediated by factors such as chromosomal location or recombination recognition sequence elements.

Transformation of murine fetal liver or adult bone marrow cells by Abelson murine leukaemia virus (A-MuLV) generates permanent cell lines which represent the pre-B stage of B-lymphocyte differentiation[6,14]. Fetal liver-derived transformants generally represent the earliest defined pre-B cell: null(non-immunoglobulin producing) cells which initially contain DJ_H complexes on both chromosomes, but which actively assemble complete V_HDJ_H complexes when propagated in culture[6]. Such cell lines will subsequently be referred to as V_H to DJ_H rearranging. The V_H to DJ_H joins which occur in such lines can be identified and isolated from appropriate cellular subclones[6,15,16]. Transformants isolated from bone marrow usually represent more mature pre-B cells which contain V_HDJ_H complexes on at least one allele upon isolation, but do not yet express light chain or have surface immunoglobulin[6,14]. The ability to study rearrangement outside of the animal, and in cells which lack surface immunoglobulin (sIg) upon isolation, provides a unique opportunity to examine the initial V_H usage pattern in the absence of antigenic or immunoregulatory selective forces acting *in vivo*. Thus, examination of the V_H segments used by such lines may identify developmentally important V_H rearrangement patterns that have not been observed previously.

Two V_H to DJ_H rearranging lines

To explore the possibility of a developmentally-related pattern of V_H segment utilization, we first characterized the V_H segments employed in six independent V_H to DJ_H joins that were identified in subclones of the V_H to DJ_H rearranging lines 22D6 and 4OE4[6,15]. Remarkably, the nucleotide sequence of the V_H portion of these rearrangements (Fig. 1) reveals that three use an identical V_H gene segment designated V_H81X (see sequence V_H81X(R) in Fig. 1; ref. 17), whereas the remaining three rearrangements use V_H gene segments closely related to V_H81X. The V_H81X gene segment and two of the related segments (designated V_HD6.96 and V_HE4.15, Fig. 1) appear to encode functional V_H regions, and the remaining V_H segment is a pseudogene (designated V_HE4.Psi; Fig. 1). These sequences all exhibit stronger nucleotide sequence homology (> 80%) to the MOPC21 V_H sequence than to V_H segments from other families (Fig. 1, Table 1), classifying them as members of the relatively small (approximately 10 members) V_H7183 gene family which has V_HMOPC21 as its prototype sequence[12]. Thus, the cell lines 22D6 and 4OE4 use a very limited set of the many V_H segments available.

J_H proximity of V_H81X and V_HE4.Psi

Because V_H81X was used at a particularly high frequency in the two V_H to DJ_H rearranging lines, it was chosen for further study. *Eco*RI-digested BALB/c liver DNA was assayed for hybridization to probes specific for V_H81X, V_HD6.96 and V_HMOPC21 (see Fig. 5 for preparation of probes) using the

Table 1 Comparison of % sequence homology in V_H coding regions

	V_HD6.96	V_HE4.15	V_HE4.Psi	V_HMOPC21	V_H141	V_H603	B1-8
V_H81X	83	87	86	81	59	57	55
V_HD6.96	—	96	88	85	ND	ND	ND
V_HE4.15		—	90	87	ND	ND	ND
V_HE4.Psi			—	88	ND	ND	ND

The sequences of V_H81X, V_HD6.96, V_HE4.Psi and V_HE4.15 are presented in Fig. 1. They are compared within the coding region to each other and to the previously published V_HMOPC21 sequence[10]. V_H81X is also compared to previously published V_H sequences[10] representative of the three V_H families immediately upstream to the V_H7183 family: V_H141 is representative of the V_HQ52 family, MCPC603 representative of the V_HS107 family, and the B1-8 sequence representative of the V_H558 family. ND indicates that the V_H segments were not compared.

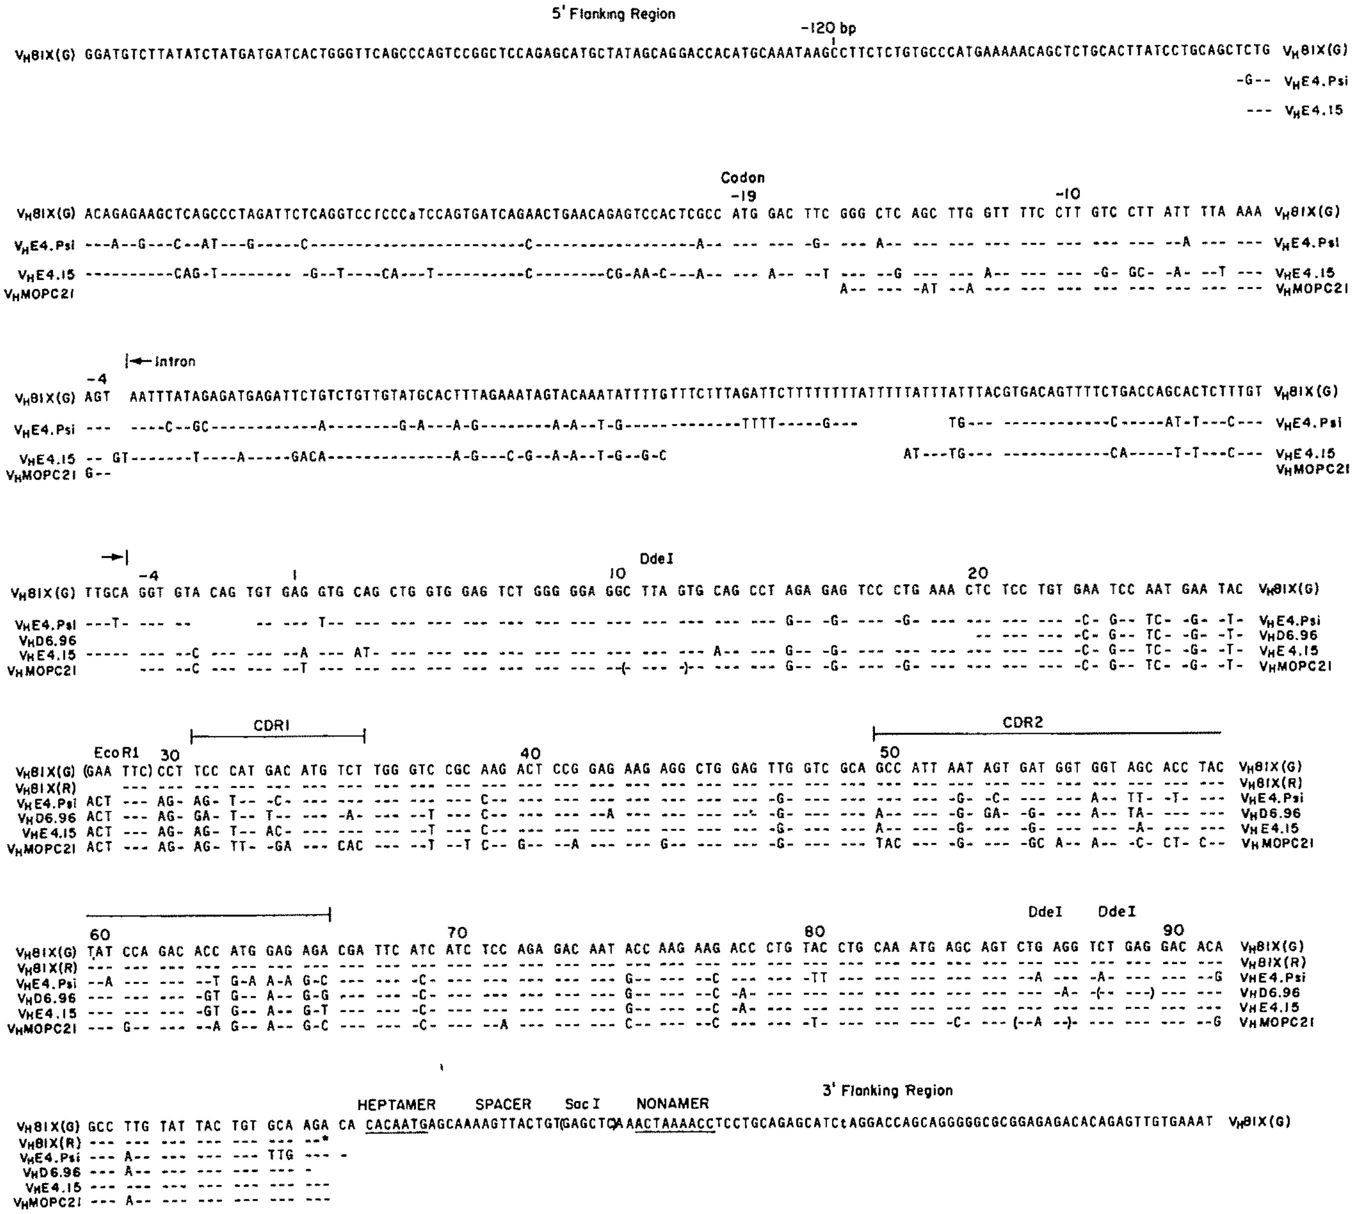

Fig. 1 Comparison of nucleotide sequences of V_H81X and related V_H segments. Rearrangements of V_H7183 segments were isolated from subclones of the V_H to DJ_H rearranging lines 22D6 and 40E4. V_H81X and V_HD6.96 rearrangements were isolated from the line 22D6-G2[6]. The V_HE4.Psi rearrangement was isolated from the line 40E4-2-26 and the V_HE4.15 rearrangement was isolated from the line 40E4-2-15[15]. Three additional rearrangements of V_H81X were isolated from two independent subclones of the line 40E4-2[15] and from the stably rearranged line 18-81A2[17]. The nucleotide sequence of the germ-line V_H81X segment (designated V_H81X(G)) was determined according to the strategy indicated in Fig. 3. The nucleotide sequence of the rearranged V_H81X segments was determined downstream from the *Eco*RI site located at codons 28–29, and often upstream from sites within the J_H region for confirmation. All four rearranged V_H81X sequences were identical and are represented by a single sequence (designated V_H81X(R)); the asterisk at the end of this sequence marks the point where the rearranged sequences begin to diverge due to heterogeneous recombination junctions with DJ_H complexes[15,17]. The nucleotide sequence of the V_HE4.Psi segment was determined from the bordering *Pst*I sites in the V_HE4.Psi-DJ_H3 rearrangement (see restriction map in Fig. 3). The V_HE4.15 rearrangement was sequenced from bordering *Pst*I sites[15]. The V_HD6.96 segment was sequenced downstream from the *Ava*II site indicated and upstream from the *Nae*I site located in the J_H4 region. The V_HMOPC21 sequence of a cDNA clone is that previously published by Bothwell *et al.*[10], and thus does not include the intron region. The V_H81X(G) sequence was used as a reference for comparison with the other sequences. A dash indicates identity and a blank within a sequence marks a deletion with respect to the corresponding bases in V_H81X(G). Changes occur in the V_H81X sequence which are invariant among all other V_H segments[8]: these include the lysine at codon 39, the leucine at codon 47, and the glutamic acid at codon 64. The V_H81X heptamer is unusual, corresponding only to that of the murine lambda light chain variable region, while the nonamer, although it differs by only one base from the consensus nonamer sequence, is unique[1,3,10,31-35]. V_HE4.Psi contains two deleterious mutations: a 7-base deletion causing a frameshift that occurs at codons −3 to −1, and a substitution creating a terminator at codon 60. All genomic cloning procedures were performed as previously described[6] and all DNA sequencing was performed by the standard Maxam and Gilbert procedure[36].

standard Southern blot procedure[18]. Under low stringency hybridization conditions all three probes identify the same set of germ-line *Eco*RI fragments (data shown for V_H81X, Fig. 2*a*, lane 2), presumably corresponding to fragments encoding the different members of the V_H7183 family. Under high stringency hybridization conditions the V_H81X probe preferentially identified a single 9.7-kb band (Fig. 2*a*, lane 3). A recombinant phage containing this fragment was isolated by screening a BALB/c germ-line DNA library with the V_H81X probe at high stringency (Fig. 3). Analysis of this recombinant clone yielded the sequence of the germ-line V_H81X segment (Fig. 1), and revealed that the 9.7-kb *Eco*RI fragment also contains the unrearranged V_HE4.Psi segment just downstream of the V_H81X segment (Fig. 3). Thus these two V_H segments are closely linked in the germ line.

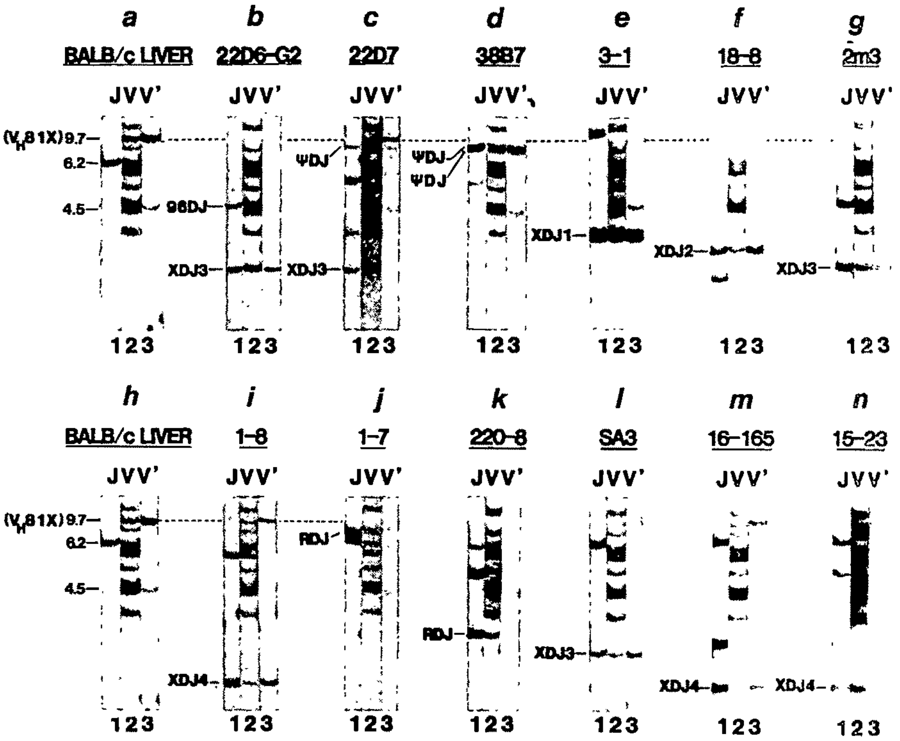

Fig. 2 Identification of V_H81X and related rearrangements in pre-B-cell lines. The derivation and growth of the A-MuLV-transformed cell lines[6,14] and the fetal liver hybridomas[20] have previously been described; other characteristics of the lines are indicated in Table 2. Approximately 10 μg DNA from the indicated sources were digested with *Eco*RI, fractionated on 1.0% agarose gels and transferred to nitrocellulose filters; duplicate blots were assayed for hybridization to either ^{32}P-labelled J_H (see ref. 6) or V_H81X (see Fig. 5) probes. Preparation of high molecular weight genomic DNA, restriction enzyme digests, agarose gel electrophoresis, nick-translations, DNA blotting and hybridizations were performed as described previously[17]. BALB/c liver DNA represents the unrearranged (germ-line) state of the immunoglobulin gene segments. The V_H81X filters were first washed at low stringency (2 × SSC, 68 °C) and then at high stringency (0.08 × SSC, 68 °C). The sizes of *Eco*RI fragments containing V_H81X and V_HE4.Psi rearranged to each of the J_H segments can be predicted from the germ-line restriction maps of the respective regions (see Fig. 3 for the germ-line V_H81X/V_HE4.Psi restriction map; ref. 2 contains the restriction map of the germ-line J_H region): for V_H81X the predicted sizes are 2.6, 2.3, 2.0 and 1.5 kb; for V_HE4.Psi the sizes are all greater than 7.8 kb, thus, a V_HDJ_H rearrangement hybridizing to the V_H81X probe at high stringency can be classified as a V_H81X-DJ_H or V_HE4.Psi-DJ_H rearrangement based on its size. V_HDJ_H rearrangements in which the V_H segment utilized has been classified as a V_H7183 family member are indicated on the figure (XDJ indicates a V_H81X rearrangement, ΨDJ a V_HE4.Psi rearrangement, 96DJ a V_HD6.96 rearrangement, and RDJ indicates that another member of the V_H7183 family was used in the rearrangement). Sizes indicated to the left on the figure are in kilobases. Lane 1: J_H probe (J); lane 2: V_H81X probe, low stringency (V); lane 3: V_H81X probe, high stringency (V').

The V_H7183 family has recently been shown to be the V_H gene family which maps closest to the J_H locus[13]. The line 22D6-G2 has utilized members of the V_H7183 family in V_HDJ_H rearrangements on both chromosomes (V_H81X and V_HD6.96; legend to Fig. 1). This line maintains at least one copy of all germ-line *Eco*RI fragments containing V_H7183 family members except for the 9.7-kb fragment which encodes V_H81X and V_HE4.Psi (compare Fig. 2*a* and *b*, lane 2). Because V_H to DJ_H joining occurs by a deletional mechanism (for example, ref. 6), this result implies that V_H81X/V_HE4.Psi are located 3′ to all other members of the V_H7183 family, and thus are the most J_H-proximal V_H segments yet characterized. This result was confirmed by analysis of many lines with two V_HDJ_H rearrangements: if at least one of the rearrangements utilized V_H81X or V_HE4.Psi (see below), the 9.7-kb germ-line *Eco*RI fragment containing these V_H segments is exclusively deleted (for example, Fig. 2*d*–*g*, *l*).

Utilization of J_H-proximal V_H segments

To determine whether preferential utilization of V_H81X and other members of the most J_H-proximal V_H family was characteristic of the pre-B-cell stage, we devised a simple hybridization assay to examine the V_HDJ_H rearrangements in a large number of lines. The four J_H segments lie within a single, germ-line 6.2-kb *Eco*RI fragment which hybridizes to a J_H probe prepared from the most 3′ portion of this germ-line fragment (Fig. 2*a*, lane 1). Assembly of a V_HDJ_H complex replaces the 5′ end of this germ-line J_H fragment, generating a novel *Eco*RI fragment which retains hybridization to the J_H probe, but which now also hybridizes to a probe homologous to the V_H segment utilized in the rearrangement (for example, Fig. 2*f*, top rearrangement). Under low stringency hybridization conditions, J_H-associated rearrangements utilizing any members of the V_H7183 family will hybridize with a V_H81X probe. Under high stringency conditions, only J_H-associated rearrangements of V_H81X itself will hybridize to the V_H81X probe; these rearrangements include V_HE4.Psi-DJ_H as well as V_H81X-DJ_H rearrangements because an *Eco*RI fragment containing a V_HE4.Psi-DJ_H rearrangement will retain an unrearranged V_H81X segment at its 5′ end (see Fig. 3). V_H81X-DJ_H and V_HE4.Psi-DJ_H rearrangements can, however, be differentiated according to the size of the *Eco*RI fragment bearing the rearrangement (see Fig. 2 legend). Any V_HDJ_H rearrangements not hybridizing to a V_H81X probe at low stringency must utilize V_H segments from more 5′ families. Because the organization of V_H segments has been most extensively characterized in BALB/c mice, all of the studies described below employed lines of BALB/c origin, except as noted.

Three V_H to DJ_H rearranging A-MuLV transformants were analysed: 22D6, 40E4 and 22D7. The rearrangements isolated from subclones of 22D6 and 40E4 have been described above (representative subclone 22D6-G2 shown in Fig. 2*b*). The third V_H to DJ_H rearranging line, 22D7, initially contained two DJ_H complexes[6], but accumulated sub-molar levels of two readily detectable V_HDJ_H rearrangements, one which utilized V_H81X and the other V_HE4.Psi (Fig. 2*c*). Thus all eight rearrangements characterized in these three V_H to DJ_H rearranging lines utilized gene segments from the V_H7183 family, with half of these rearrangements utilizing V_H81X. Fourteen A-MuLV transformants which had assembled V_HDJ_H rearrangements prior to isolation and which did not undergo further rearrangement during propagation (referred to as stably rearranged) have been assayed as described above. Of the 22 V_HDJ_H rearrangements identified in these lines[6], at least 10 utilized members of the V_H7183 family, predominantly V_H81X and V_HE4.Psi (Table 2, Fig. 2*d*–*k*). Several rearrangements did not use V_H segments which hybridized to the V_H81X probe (for example, the lower rearrangement in Fig. 2*f*). The V_H segments in five of these rearrangements were characterized by nucleotide sequence

Table 2 V_H segment utilization in the V_HDJ_H rearrangements of pre-B-cell lines

The data presented represent a composite of the DNA/RNA hybridization assays and the nucleotide sequence analysis presented in the paper. The number of V_HDJ_H rearrangements in the stably rearranged A-MuLV transformants was previously determined[6]. The number of rearrangements listed for the V_H to DJ_H rearranging lines 40E4 and 22D6 indicates the number of independent V_HDJ_H rearrangements molecularly cloned and characterized from subclones of these lines (see Fig. 1). The V_H to DJ_H rearranging line 22D7 was described in the text. The other V_H to DJ_H rearranging lines were analysed for RNA expression only; the expression data are listed as '+' or '−' under the appropriate column. For the stably rearranged lines, ? in the last two columns indicates that a V_HDJ_H rearrangement co-migrated with a germ-line V_H7183 fragment (for example, upper rearrangement in Fig. 2*g*), and thus it could not be determined if this rearrangement utilized a V_H7183 segment or a V_H segment from a more 5′ V_H family.

* Rearrangements which have been molecularly cloned and sequenced. These include five rearrangements which have utilized segments from families 5′ to the V_H7183 family (G.D.Y., T. K. Blackwell, K. Kruger, N. E. Kohl, R. dePinho, M. G. Reth & S.W.A., unpublished data): four different V_H segments from the very large V_H558 family were isolated in rearrangements from the lines 220-8, 223-18, 204-1-7 and 298-8 while the V_H segment in the rearrangement isolated from the line 18-8 corresponded to the prototype sequence of a more 5′ V_H family, V_H36-60[19]. The RNA assay (see Fig. 5) revealed that V_H segments from the V_HQ52 and V_HS107 families were utilized in at most one rearrangement each in the stably rearranged lines.

† Derived from C57L strain, identical in Igh *z* haplotype to BALB/c[12].

analysis (see Table 2); four were different members of the very large (up to 50 members) V_H558 family, and the other corresponded to the prototype sequence from one of the more 5′ V_H families, V_H36-60[19].

V_H expression in A-MuLV transformants

Both productive and non-productive rearrangements are expressed at the RNA level in A-MuLV transformed cell lines[17]; thus, definition of the V_H-specificity of the expressed RNA can be used to characterize the V_H segments rearranged in these lines. This approach, which can be used to screen efficiently many lines with several different probes, was used to further characterize V_H segment utilization within the V_H7183 family, and also to examine more readily V_H segment utilization from other families. Poly(A)-containing RNA prepared from 24 A-MuLV-transformed cell lines was slot-blotted onto nitrocellulose filters and assayed for hybridization to probes prepared from six different V_H segments: V_H81X, V_HD6.96 and V_HMOPC21, which are members of the V_H7183 family (see above); V_HQ52 and V_HS107, which represent the V_H families immediately upstream to the V_H7183 family[12,13]; and V_H1-7, a member of the V_H558 family (see legend to Figs 4, 5). Under

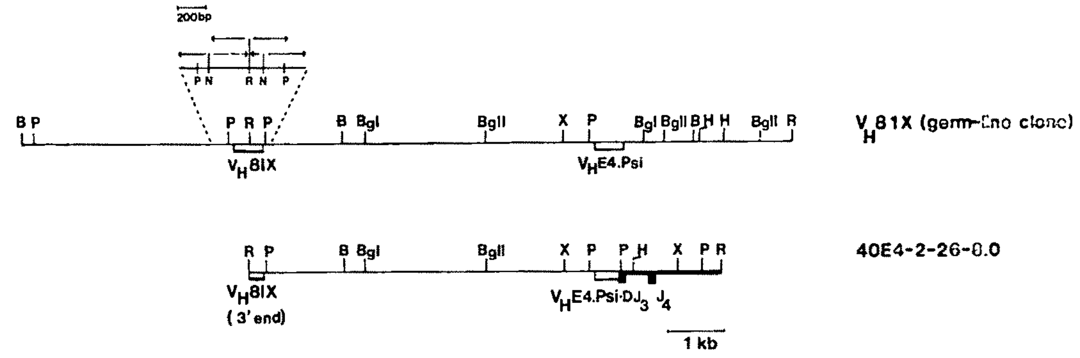

Fig. 3 Linkage of V_HE4.Psi and V_H81X in the germ line. A partial restriction map of a recombinant Charon 4A phage containing a 20-kb germ-line insert, including the 9.7-kb V_H81X/V_HE4.Psi-containing *Eco*RI fragment, is presented. This phage was isolated from a library of *Hae*III/*Alu*I partially digested BALB/c sperm DNA[37] as described in the text. An enlargement of the region surrounding the V_H81X segment is depicted above the map with arrows indicating the strategy utilized to obtain the V_H81X(G) sequence. The map of the cloned V_HE4.Psi rearrangement[15] is presented below the germ-line map, with the restriction maps aligned to demonstrate that the 5' region of the V_HE4.Psi rearrangement is identical to the 5' end of the 9.7-kb V_H81X-containing germ-line *Eco*RI fragment. The map diverges at the point of recombination of the V_HE4.Psi segment with the DJ_H region (the J_H region is indicated by the bold line). Partial nucleotide sequence analysis also confirmed the identity of the 5' ends of these two clones. The restriction sites are marked as follows: B, *Bam*HI; *Bgl*, *Bgl*I; *Bg*II, *Bgl*II; H, *Hin*dIII; N, *Nco*I; P, *Pst*I; R, *Eco*RI; *X*, *Xba*I.

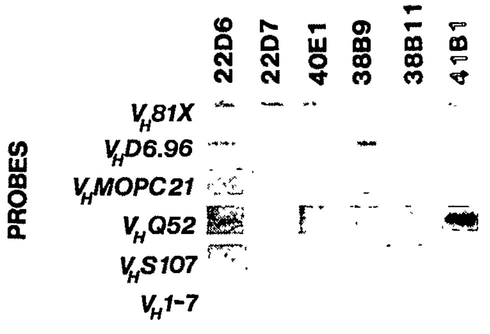

Fig. 4 V_H expression in V_H to DJ_H rearranging A-MuLV transformants. Poly(A)-containing RNA was prepared from the indicated sources as previously described[17]; 0.5 μg of this RNA was denatured in 6% formaldehyde, 50% formamide, 1× SSC at 68 °C for 10 min, a fourfold excess of 20× SSC was added, and the samples were then blotted onto nitrocellulose filters using a slot-blotting apparatus (Schleicher and Schuell-minifold II) The filters were baked, hybridized to probe, and washed as described previously[17]. Identical blots were hybridized with the ^{32}P labelled V_H-specific probes indicated (V_H7183 probes described in Fig. 5. the V_H1-7 segment was prepared from a rearrangement isolated from the A-MuLV transformant 204-1-7 (see Table 2) and is a member of the V_H558 family; all other V_H-specific probes extensively characterized by G.D.Y. and F.W.A., in preparation) Approximately 1.0 μg of total RNA prepared from 4-week spleens probed at high stringency served as positive control and is shown in far right in Fig. 5. The exposures depicted were washed at low stringency (1.0× SSC, 68 °C) except for the blot probed with V_H1-7 which was washed at high stringency (see Fig. 5) The probe for each set of samples is indicated on the left of the figure.

high stringency conditions these probes strongly hybridize only to identical or very homologous sequences whereas at low stringency they hybridize to additional, less closely related, members of their family (see Fig. 5 legend). Six V_H to DJ_H rearranging lines were assayed for V_H-specific expression. These lines contain subpopulations which have formed complete V_HDJ_H complexes in culture[6,14,15]. All six lines revealed low levels of expression of RNA sequences which hybridized to V_H81X and V_HD6.96 but not to V_HMOPC21 (Fig. 4; the RNA sequences which hybridized to the V_H81X and V_HD6.96 probes were the size of *u* mRNA—data not shown). Only one line, 41B1, expressed V_H sequences related to any of the other probes (Fig. 4). These results indicate that the V_H sequences expressed in these lines generally represent a subset of the V_H7183 sequences that are more closely related to V_H81X and V_HD6.96 than to V_HMOPC21. Fifteen stably rearranged A-MuLV transformants were assayed for V_H-specific expression (Fig. 5). Ten of these lines expressed V_H sequences from the V_H7183 family, of which five expressed V_H81X and five expressed sequences closely related to V_HD6.96 (Fig. 5, Table 2). Tested V_H probes representing families upstream of V_H7183 were expressed in many fewer lines than were V_H81X-related segments (Fig. 5, Table 2). This is consistent with the results described above.

In summary, 23 A-MuLV-transformed cell lines of BALB/c origin were analysed for V_H usage by nucleotide sequencing and DNA and/or RNA hybridization studies. The V_H to DJ_H rearranging lines almost exclusively used V_H7183 gene segments in rearrangements, whereas the stably rearranged lines preferentially utilized V_H7183 segments, but also used segments from other V_H families (Table 2).

V_H81X usage in fetal liver hybridomas

To show that preferential use of V_H81X and related V_H segments was not confined to A-MuLV-transformed cell lines, we examined a set of 12 fetal liver hybridomas that were derived from BALB/c or (BALB × SJL) F$_1$ mice[20]. We identified a total of 10 possible V_HDJ_H rearrangements in these lines by methods described previously[6] (the remaining J_H rearrangements were DJ_H complexes). Using the genomic DNA hybridization assay described above, we found that V_H81X was utilized in three of these rearrangements (Fig. 2*l*–*n*).

Structure of V_H81X

Characterization of the V_H segments utilized by pre-B-cell lines allowed identification and nucleotide sequence analysis of five members of the most J_H-proximal V_H family in the BALB/c mouse strain. V_H81X is the most highly divergent of these five related V_H segments; its sequence is striking in that changes occur at several positions which are invariant among all other V_H genes (see Fig. 1 legend). In particular, the replacement of the highly conserved tryptophan at codon 47 by leucine may disrupt the heavy chain structure and affect binding with light chain (M. Reth, personal communication). The recombination recognition sequences for V_H81X, which mediate V_H to DJ_H joining, are also quite distinctive (see Fig. 1 legend). It is notable that the V_H81X segments utilized in the four sequenced V_H81X-DJ_H rearrangements are identical to the germ-line V_H81X segment (Fig. 1). This result is consistent with a lack of selection for somatic mutants in the early developmental stages represented by these lines.

Chromosomal location and V_H utilization

Our studies have revealed a striking consistency in the pattern of V_H usage in pre-B-lymphocytic cell lines. A set of the most J_H-proximal V_H segments, typified by V_H81X, were highly preferentially rearranged in many A-MuLV transformants derived from both fetal liver and adult bone marrow. As discussed earlier, it is unlikely that selection for particular immunoglobulin specificities has influenced our results. It is also unlikely that our results represent an artefact related to the use of permanent cell lines; we have observed this phenomenon in both A-MuLV-

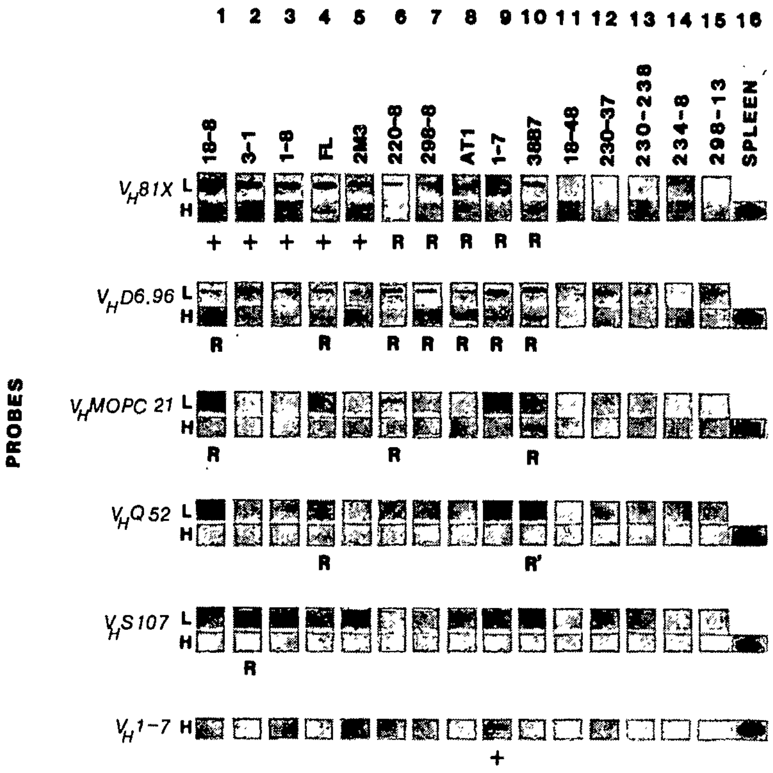

Fig. 5 V_H expression in stably rearranged A-MuLV transformants. Poly(A)- containing RNA was prepared from the indicated lines and processed as in Fig. 4. Exposures of blots washed at low (1.0× SSC, 68 °C) and high (0.1× SSC, 68 °C) stringency, as indicated for each probe, are shown. The blot probed with V_H1-7 was washed only at high stringency; this was because closely related unrearranged V_H gene segments have been found to be expressed in most pre-B-cell lines (G.D.Y. and F.W.A., in preparation). The V_HQ52 probe hybridizes to RNA from the line 38B7 because the V_HQ52 probe hybridizes to V_HE4.Psi sequences at low stringency (G.D.Y. and F.W.A., in preparation), not because of V_HQ52 expression. The hybridization to the V_H81X and V_HD6.96 probes has been determined to be of normal μ-size (data not shown). A '+' under a slot indicates that the V_H expressed by the line is completely homologous to the V_H fragment used as a probe, as judged by Southern hybridization data and by maintenance of hybridization even at high stringency. An 'R' under a slot indicates that a line expresses V_H sequences very closely related to the V_H fragment used as probe. An R' indicates low-level hybridization that may or may not be due to hybridization within a V_H family. Preparation of probes: The V_H81X fragment was prepared from the germ-line clone by digesting at the *Eco*RI and *Sac*I sites indicated by brackets in the V_H81X(G) sequence (Fig. 1) and purifying the approximately 220-bp fragment spanned by these sites. The V_HD6.96 fragment was prepared by digesting at the *Ava*II and *Dde*I sites indicated (Fig. 1) and isolating the intervening fragment. The V_HMOPC21 fragment was prepared from a cDNA clone by digesting at the *Dde*I sites indicated in the V_HMOPC21 sequence (Fig. 1) and isolating the approximately 200-bp fragment released. All fragments contained V_H coding regions only and spanned both hypervariable regions.

transformed pre-B cells and fetal liver (pre-B) hybridomas, and have recently confirmed these findings in studies of normal pre-B cells[21].

Examples of developmental control related to chromosomal organization are found with mammalian globin genes[22], silk moth chorion genes[23], and immunoglobulin genes[6,24]. Here we demonstrate that members of the most J_H-proximal V_H family (V_H7183) are rearranged preferentially in pre-B-cell lines. Furthermore, there is biased usage within the V_H7183 family: the most J_H-proximal segments (V_H81X/V_HE4.Psi) are used most frequently, while a subset of closely related segments (typified by V_HD6.96 and V_HE4.15) are used more frequently than the remaining members of the family (typified by V_HMOPC21). Although fetal liver-derived A-MuLV transformants almost exclusively utilize V_H segments from the V_H7183 family, V_H segments from more 5′ families are represented in approximately half the rearrangements made by marrow-derived A-MuLV transformants. Because the fetal liver-derived lines generally represent a less mature stage of pre-B-cell differentiation than marrow-derived lines[6], this result implies that the repertoire of expressed V_H segments expands during pre-B-cell development. Our data suggests that V_H segments from more 5′ families are randomly represented in rearrangements in pre-B-cell lines; many of these rearrangements used different members of the largest V_H family (V_H558), which may contain up to half of the entire V_H repertoire. The simplest mechanism for the preferential rearrangement of V_H7183 segments would involve their relative chromosomal location: for example, potential recombinases may recognize J_H-proximity in the context of one-dimensional scanning[5]. J_H-proximity is not, however, the sole determinant of preferential rearrangement because V_HE4.Psi is located 3′ to V_H81*X* and is used less frequently.

Functional significance of biased V_H usage

The distinctive amino acid sequence encoded by V_H81X has never been found to be expressed in lines representing mature cell types; furthermore, V_H7183 segments are rarely seen in the apparently random representation of V_H segments found in mature cell types[8]. This reveals a major difference in the repertoire of V_H segments expressed by precursor and mature B-cell populations. The apparently random and extremely diverse set of V_H segments expressed in mature populations could derive from an initial population expressing a biased repertoire by various methods. One such is selection against cells with V_H81X rearrangements occurring during pre-B-cell development; for example, if V_H81X-encoded heavy chains could not associate with light chains, sIg formation would be impossible. Alternatively, even if V_H81X was over-represented in the initial sIg$^+$ B-cell population, other clonotypes might be selectively expanded.

Although we have observed preferential V_H7183 segment rearrangement in strains other than BALB/c, in at least one strain V_H81X is not the most J_H-proximal segment (G.D.Y., M. G. Reth and F.W.A., unpublished data). Thus, different V_H segments may be preferentially rearranged in different strains. This preferential rearrangement may simply be a by-product of the recombinational mechanism, or the rearrangement of the most J_H-proximal V_H segments *per se* may be important in early B-cell differentiation, for example, by serving as a substrate for subsequent *V*-replacement mechanisms. On the other hand, expression of preferentially rearranged segments could play an important role in the developing immune system. Although there are no direct precedents for our results, many studies have suggested that the ability to respond to different antigens follows an ordered developmental sequence[25–30]. It has been shown that highly restricted sets of anti-DNP and anti-TNP antibodies (clonotypes) reproducibly appear during early murine ontogony[30]. Recently, Riley and Ogata (personal communication) have cloned the cDNA for one heavy chain involved in an early DNP response. The V_H segment utilized in the variable region coding for this heavy chain is, remarkably, far more homologous to V_HE4.15 and V_HD6.96 (greater than 95% homology to both) than to any V_H segment previously identified. Thus an antibody made early in development is encoded by a V_H segment which rearranges preferentially in early B-lymphoid cells, suggesting that programmed rearrangement may underlie the programmed appearance of clonotypes.

Rapid variability in optical polarization of the quasar-like object OJ287

Anjani K. Kulshrestha, U. C. Joshi & M. R. Deshpande

Physical Research Laboratory, Ahmedabad-380009, India

OJ287 (0851+20) is one of a small group of quasar-like objects, the BL Lac group. It has a featureless optical nonthermal continuum, a relatively flat radio spectrum, a high degree of linear polarization at radio and optical wavelengths, it is extremely compact and displays a strong rapid variability at all wavelengths. Rapid variations in the optical flux of OJ287 with a period of about 40 min were observed by Visvanathan and Elliot[1] and by Frohlich *et al.*[2]. At 1.25 μm even more rapid but non-periodic variations were reported by Wolstencroft *et al.*[3]. We report here observations of rapid and strong variations in the degree of linear polarization of the optical flux of OJ287. We conclude that if the radiation observed from the variable component was of synchrotron nature, then there must be a high degree of relativistic beaming in OJ287. On the other hand, if the variable flux is assumed to be the inverse-Compton scattered flux and relativistic effects are not invoked, OJ287 must have a very compact central source, probably a black-hole accretion-disk system.

The photopolarimetric observations of OJ287 in the ultraviolet, blue, visible, red and infrared (UBVRI) wavebands were made using the Minipol instrument[4], with GaAs detectors (cooled to dry ice temperatures), on the 1.55-m telescope of the University of Arizona at Mt Catalina on 10-12 January 1984. Normalized Stokes parameters, Q and U, and their errors were calculated from a least squares analysis of the data, and the degree of linear polarization ($P=(Q^2+U^2)^{1/2}/I$) and position angle ($\theta=\frac{1}{2}\tan^{-1}Q/U$) were calculated from these quantities, where I is the intensity. Sky observations were made approximately every 15 min and the results were obtained from the data corrected for sky background. Instrumental polarization was negligible in comparison with that of the source. Photometric calibrations were made on all nights by observing the star HR382.

Polarization in the R band was monitored from 09:10 to 09:50 UT on 10 January and from 09:55 to 10:50 UT on 11 January (Fig. 1). On 10 January, polarization dropped from 18 to 14% (standard error in polarization, $\sigma_p\approx0.8\%$) in about 20 min. During this interval the adjacent sky polarization varied very little (2.7-3.1%, $\sigma_p\approx1\%$). Two polarization peaks were observed on 11 January; first the degree of polarization dropped from 13% to 9% in about 20 min, and then it increased again to 14% in the next ~15 min. On 12 January, polarization was monitored in I band from 08:50 to 10:00 UT (Fig. 2). Three asymmetric saw-tooth shaped variations were observed. The polarization peaks were separated by about 25 min, and the degree of polarization varied from 12 to 16% ($\sigma_p\approx0.9\%$). In this interval, four sky observations were made; the sky polarization varied from 1.7 to 2.2%, and the variations in the sky brightness were <0.1 mag. The magnitude, linear polarization, and position angle measurements made in the UBVRI bands on the same date, just after the above-mentioned observations, are shown in Table 1. The observed wavelength-independence of the degree and orientation of polarization indicates that the variations

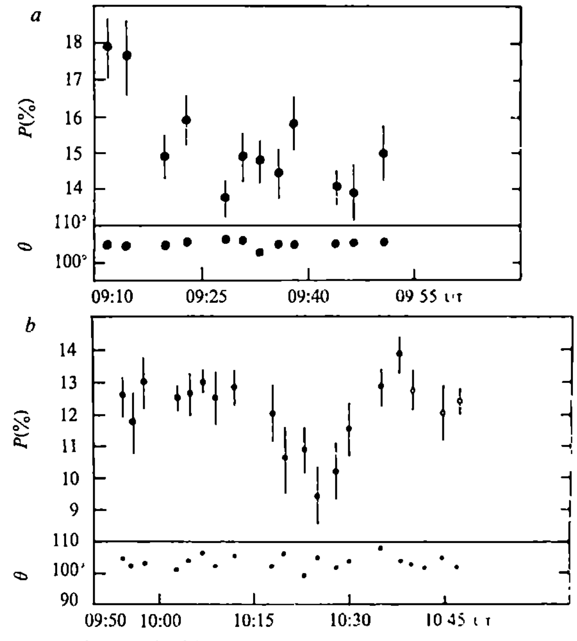

Fig. 1 Time variability of the percentage linear polarization (P) and the position angle (θ) of OJ287 in R band. *a*, 09:10-09:50 UT on 10 January 1984; *b*, 09:55-10:50 UT on 11 January 1984. The error bars have a total length of 2 s.d.

Table 1 Photopolarimetric observations of OJ287 on 12 January 1984

Waveband (λ)	Magnitude	P ($\pm\sigma_P$) (%)	θ ($\pm\sigma_\theta$) (deg)
U (0.36 μm)	14.3	13.4 (±0.8)	97 (±1.7)
B (0.44 μm)	15.1	13.6 (±0.6)	94 (±1.3)
V (0.55 μm)	14.6	13.5 (±0.4)	93 (±0.8)
R (0.7 μm)	14.0	14.6 (±0.8)	94 (±1.6)
I (0.8 μm)	13.3	13.7 (±0.4)	94 (±0.8)

observed in I band were present at least in the whole optical region, that is from U to I bands. The total optical flux, received at Earth, amounts to 2.77×10^{-11} erg s^{-1} cm^{-2}.

The general trend of the observed variations can be described as follows: the degree of polarization fluctuates by ~4% on a time scale of ~25 min; the variations are saw-tooth shaped with the rising edges much steeper compared to the falling ones, and these fluctuations recur at very short time-intervals.

The optical polarization of the star RY Tau was observed on 9 January for ~25 min and the degree of polarization was found to lie between 3.2 and 3.3% ($\sigma_p \approx 0.1\%$). The amplitudes of the observed variations in the polarization of OJ287 are very large (~4%) and, thus, these variations cannot be attributed to systematic instrumental effects.

For a source redshift of 0.306 (ref. 5), $H_0 = 75$ km s^{-1} Mpc^{-1} and $q_0 = 0$, the observed absolute optical luminosity equals 4.8×10^{45} erg s^{-1}. To produce variations in the degree of polarization by as much as 4%, the absolute luminosity of the variable component, L, should be $\geqslant 2\times10^{44}$ ergs s^{-1}. The observed period of 25 min corresponds to a variability time scale, τ, of ~19 min in the rest-frame of the source.

A severe Compton problem (the paradox first described by Hoyle *et al.*[6]) arises if we assume that the variable component was radiating by synchrotron process. This trouble can be removed by invoking bulk relativistic streaming. The requirement that the synchrotron lifetime of electrons be at least equal to the variability time scale gives the value of relativistic Doppler factor: $\delta \geqslant 15$, where $\delta = (1-\beta^2)^{1/2}/(1-\beta\cos\phi)$ where β is the bulk velocity in units of c, and ϕ is the angle between the direction of motion and the direction along the line of sight. An alternate way of overcoming the Compton problem is to assume that the observed radiation was coming from a very small instability, far from the central source, which derived its energy from the central source (in an unspecified way). Other mechanisms, such as small pitch angle coherent synchrotron emission[7] or the reacceleration of electrons[8], could eliminate the Compton problem. However, note that the models which can explain an isolated rapid variation are not necessarily capable of explaining this kind of rapidly recurring variations.

Rees[9] has shown that rapid periodic variations can be explained using models which invoke relativistic expansion, provided the source is optically thick. An interesting feature of this kind of expanding-source models is that in any outburst, at a given frequency, the source should brighten faster that it fades. This feature would fit to our data when both the variable and the basic synchrotron components of OJ287 were radiating in the same magnetic field configuration.

The other possibility is that the radiation observed from the variable component was inverse-Compton scattered flux from lower frequency photons. The particles which scatter the photons, themselves present some opacity to the photons and thus set a lower limit to the possible variability time scales for an outburst with given luminosity. On the basis of this type of consideration, Fabian[10] has derived a minimum time scale of variation, $\tau \geqslant L(\mathrm{erg\,s^{-1}})/2\times10^{42}\eta$, where η is the efficiency with which matter is converted to energy. Our data imply a value of $\eta \geqslant 10\%$. For the case of accretion onto massive black hole, such a high value of efficiency is possible only if the accreting material possesses anguar momentum[11]. If we consider the source to be isotropic and free from bulk relativistic motions, and if its luminosity does not significantly exceed the Eddington limit, due to emission of pulsar-type radiation, then by equating the luminosity of the variable component to Eddington luminosity and taking the appropriate radius of the accretion disk round a black hole to be about five times the Schwarzschild radius, the minimum value of possible variability time scales is ~1.3 min which is one-fifteenth of the observed time scale. The supermassive stars would give about 100 times more than this for the minimum time scales. Thus, our observations suggest that the central core of OJ287 is probably a black hole accretion-disk system.

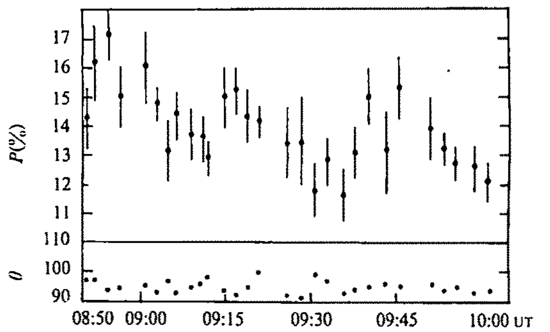

Fig. 2 Time variability of P and θ of OJ287 in I band, 08:50–10:00 UT on 12 January 1984.

Outer-core geostrophic flow and secular variation of Earth's geomagnetic field

J. L. Le Mouël

Laboratoire de Géomagnétisme et Paléomagnétisme (ERA 922),
Institut de Physique du Globe, Tour 14, 4 Place Jussieu,
75230 Paris Cedex 05, France

In studies of the temporal variations of the main internal geomagnetic field (the secular variation or SV), it is usual to consider separately the variations of the dipolar and non-dipolar parts which appear to have different time constants. The mechanism that is generally invoked to explain the generation of SV is the advection of the lines of force of the main field by the highly conducting fluid at the top of the core. Such a mechanism involves the main field as a whole and it is not clear *a priori* why its two parts should behave separately. I show here that the Coriolis force will probably dominate the force budget at the top of the core and that, in such a case, the motion of the fluid involves the two parts of the field in a different way; in particular, the existing axial dipolar component is not re-engaged in the process which builds up the SV.

Let us consider the Navier-Stokes equation in the outer layers of the core:

$$\rho(\delta\mathbf{u}/\delta t + \mathbf{u}.\nabla\mathbf{u}) = -\nabla p + \mathbf{J}\times\mathbf{B} - 2\rho(\mathbf{\Omega}\times\mathbf{u}) + \rho\nu\Delta^2\mathbf{u} - \rho g\mathbf{n} \tag{1}$$

where ρ is the density, $\mathbf{u}$ the velocity, p the pressure, $\mathbf{J}$ the electric current density, $\mathbf{B}$ the magnetic field, $\mathbf{\Omega}$ the Earth's rotation, ν the kinematic viscosity, $\mathbf{n}$ the unit radial vector, g the gravity.

In the frozen-flux approximation, where the core fluid is considered to be a perfect conductor[1-5], the SV observed outside the core depends only on the (horizontal) motion $\mathbf{u}$ of the fluid at the core-mantle boundary, more exactly below a thin boundary layer. If the flow is assumed to be large scale, its velocity can be estimated from SV data: its order of magnitude U is found to be 10^{-4} m s^{-1} (see ref. 6; the value of 0.2^{0} yr^{-1} for the westward drift rate corresponds to 4×10^{-4} m s^{-1}). In this large-scale hypothesis, both the Rossby number R and the Ekman number E are quite small. Taking $L=10^{6}$ m as a characteristic horizontal length of $\mathbf{u}$, we have $R=U/\Omega L\simeq10^{-6}$ and $E=\nu/\Omega L^{2}\ll1$, whichever value we adopt for the poorly known kinematic viscosity of the core.

As for the time constant of $\mathbf{u}$, the SV field can change significantly—by half its value—in, say, 10 yr (refs 7, 8). But the acceleration term $\rho\delta\mathbf{u}/\delta t$ is fairly negligible ($<10^{-3}$) compared with the Coriolis force.

Let us now consider the Lorentz force $\mathbf{J}\times\mathbf{B}$. If the field is purely poloidal in the external layers of the core, $B\simeq5\times10^{-4}$ T, and we get: $|(\mathbf{J}\times\mathbf{B})|/|2\rho(\mathbf{\Omega}\times\mathbf{u})|\simeq B^{2}/2\mu\rho\Omega LU\simeq10^{-3}$. It is possible that a toroidal field also exists in the outer layers of the core, as often predicted by dynamo theory, and as is required for electromagnetic core-mantle coupling. But, even if this toroidal field does exist and is intense in the body of the core (up to 10 times the poloidal field), it is certainly less intense in the neighbourhood of the (nearly) insulating mantle. More precisely, let β be the ratio of the dominant part of the horizontal Lorentz force to the horizontal Coriolis force. It is easily shown that $\beta\simeq B_{r}B_{T}f(\theta)/(2\mu\rho\Omega lU\cos(\theta))$, where B_{r} is a typical value of the radial component of the poloidal field at the core-mantle boundary, B_{T} a typical value of the toroidal field $\mathbf{B}_{T}$ in the body of the core, l a characteristic vertical scale of $\mathbf{B}_{T}$. $f(\theta)$ depends on the variation of $\mathbf{B}_{T}$ with colatitude θ. If, as is generally assumed, $\mathbf{B}_{T}$ is antisymmetrical with respect to the Equator and vanishes on the Equator (for example, if $\mathbf{B}_{T}$ is a P_{2}^{0} toroidal field due to the differential rotation of the core in the presence of the axial dipolar field), $f(\theta)/\cos(\theta)\simeq1$. When $l=10^{6}$ m then β has approximately the same numerical value as B_{T} expressed in tesla, that is to say 5×10^{-2} in the most unfavourable case. If l is smaller, as suggested by Benton and Muth[9], due to the possibility of a strong gradient of B_{T} near the core-mantle boundary, β is, of course, larger. If not, or if the toroidal field is of the same order of magnitude as the poloidal one, the horizontal projection of equation (1) reduces nearly everywhere to the geostrophic approximation in its usual form:

$$2\rho(\mathbf{\Omega}\times\mathbf{u})_{\mathrm{H}}+\nabla_{\mathrm{H}}p=0 \qquad (2)$$

where H indicates horizontal. Equation (2) must be complemented by the radial component of equation (1) whose principal part is the hydrostatic equation. Then

$$\mathbf{u}=(2\rho\Omega\cos\theta)^{-1}\mathbf{n}\times\nabla_{\mathrm{H}}p \qquad (\theta\neq\pi/2) \qquad (3)$$

Let us now recall an important result due to Backus[3]. Let B_{r} be the radial component of the geomagnetic field $\mathbf{B}$ at the core-mantle boundary, $\dot{B}_{r}$ its time derivative. These quantities are related through the equation

$$\dot{B}_{r}=\mathrm{div}_{\mathrm{H}}(\mathbf{u}B_{r}) \qquad (4)$$

It follows directly that all motions of the form

$$\mathbf{u}=(B_{r})^{-1}(\mathbf{n}\times\nabla_{\mathrm{H}}\psi), \qquad (5)$$

where ψ is any well behaved function of longitude ϕ and colatitude θ, are in the so-called null space of $\mathbf{B}$ that is generate no secular variation $\dot{\mathbf{B}}$ from $\mathbf{B}$.

From equations (5) and (3), the geostrophic motion (3) is in the null space of the axial-dipole field: if, at a certain epoch, the geomagnetic field happens to be that of an axial dipole, it will remain axial dipolar and unchanged.

In general, at the core-mantle boundary,

$$B_{r}=\alpha_{1}^{0}\cos\theta+\Sigma_{n,m\neq1,0}(\alpha_{n}^{m}\cos m\phi+\beta_{n}^{m}\sin m\phi)\,P_{n}^{m}(\cos\theta)$$

Equation (4) being linear, it follows that the axial dipolar part of $\mathbf{B}$ is not involved in the generation of SV by the geostrophic motion $\mathbf{u}$. Let $\mathbf{B}_{1}$ denote the axial dipolar component of $\mathbf{B}$, $\mathbf{B}_{\mathrm{nda}}$ the non-dipolar-axial field, that is $(\mathbf{B}-\mathbf{B}_{1})$. The behaviour of SV can be summarized by the two equations

$$\dot{\mathbf{B}}_{1}=\mathbf{F}_{1}(\mathbf{u},\mathbf{B}_{\mathrm{nda}})$$

and

$$\dot{\mathbf{B}}_{\mathrm{nda}}=\mathbf{F}(\mathbf{u},\mathbf{B}_{\mathrm{nda}}) \qquad (6)$$

The fact that the existing axial dipolar field is not used in the process by which the field is changed provides a simple explanation of why the secular variation of this axial dipolar field (the geological field) does not involve the same time constant as the secular variation of the non-dipole field (all the better since the westward drift of the external layers of the core, which is sometimes considered as the prominent stable part of $\mathbf{u}$, does not generate any $\mathbf{B}_{1}$ from $\mathbf{B}_{\mathrm{nda}}$).

Let us now assume that the frozen flux approximation still holds for time spans of some thousands of years[10] and consider a reversal of the geomagnetic field: the non-dipole field cannot disappear during the process, otherwise the whole process would stop (equation (6)). Such an extrapolation to long time spans is certainly speculative. But, for time spans short enough for the frozen-flux approximation to hold, a geostrophic flow in the upper layers of the core implies some of the observed features of the secular variation of the geomagnetic field (my arguments in favour seem to fail only if the unobservable toroidal field is both very intense and rapidly varying near the core-mantle boundary).

I acknowledge fruitful discussions with R. Hide and G Backus. IPGP contribution 788.

Stress corrosion in a borosilicate glass nuclear wasteform

A. E. Ringwood & P. Willis

Research School of Earth Sciences, Australian National University,
Canberra 2601, Australia

Most current technologies for the incorporation of high-level nuclear wastes in borosilicate glass wasteforms on a large scale yield products characterized by marked internal stresses developed during cooling and also around crystalline inclusions. We discuss here a typical borosilicate glass wasteform which, when exposed to water vapour and water for limited periods, exhibits evidence of stress corrosion cracking arising from the interaction of polar OH groups with stressed glass surfaces. Glass wasteforms may experience similar stress corrosion cracking when buried in a geological repository and exposed to groundwaters over an extended period. This would increase the effective surface areas available for leaching by groundwater and could decrease the lifetime of

the wasteform. Conventional leach-testing methods are insensitive to the longer-term effects of stress corrosion cracking. We suggest that specific fracture-mechanics tests designed to evaluate susceptibility to stress corrosion cracking should be used when evaluating the wasteforms for high-level nuclear wastes.

The most important property which is used to characterize borosilicate glass wasteforms is their leaching performance in water and aqueous solutions. Most glasses which have been characterized by leach tests have been produced on a small scale in laboratory conditions. Melting is typically carried out under well-controlled conditions above the liquidus, so that there are no crystalline phases present. In many cases, the glasses have been annealed during cooling to eliminate internal stresses. The borosilicate glasses produced by current technologies for the immobilization of high-level nuclear waste (HLW) on a full engineering production scale differ from these 'ideal' laboratory-produced glasses in two important respects. First, they usually contain a few per cent of dispersed crystalline phases, arising either from incomplete solution of the HLW or from crystallization during slow cooling, after the glass has been poured into canisters[1,2]. Second, when HLW-glasses are cooled in commercial-sized canisters, they are subjected to thermal stresses which cause extensive cracking[3,4]. Typically, this leads to an increase in the surface area of the glass by about a factor of 10 (ref. 3). Moreover, the remaining domains of uncracked glass are themselves subjected to quite strong internal stress fields.

These characteristics are displayed by a sample of borosilicate glass containing about 25% of simulated HLW produced by the 'in-canister' melting process at the US Department of Energy plant at Savannah River, South Carolina. This technology is the accepted 'back-up' process for the joule-heated ceramic melter on-site. The chemical composition of this glass as determined by electron microprobe analysis is as follows: SiO_2, 46.0; TiO_2, 0.3; Al_2O_3, 4.2; Fe_2O_3, 14.8; MnO, 3.3; NiO, 1.5; CaO, 5.3; Na_2O, 15.2; $B_2O_3+Li_2O$, 9.4 wt%. Note, however, that the phenomena discussed here are not specific to glasses of any singular chemical composition, or produced by any one technology, but are generic to HLW glasses produced on a commercial scale by most current technologies because of the residual stresses which these processes induce in the final products.

The sample which was studied (Fig. 1) is bounded by generally conchoidal fracture surfaces. Small impacts readily cause spalling, demonstrating the existence of a pervasive state of internal stress. Numerous crystalline inclusions are visible. Large numbers of sharp cleavage steps are also present (Figs 1, 2). In many cases, cleavage steps propagate outwards from crystalline inclusions (Fig. 2).

Close examination of cleavage steps on surfaces of glass which have been exposed to the atmosphere for ~2 yr show that distinct cracks up to 5 mm long have formed at the base of many of the steps. In contrast, cracks beneath cleavage steps rarely occur on freshly fractured surfaces. The common occurrence of these cracks on surfaces which have been exposed to the atmosphere for an extended period suggests a causal relationship. Related observations and interpretation by Wiederhorn and others[5-8] suggests that the cracks have been caused by stress corrosion in the presence of atmospheric moisture. This phenomenon has been widely recognized in stressed glasses in the presence of polar solvents (such as, water) and also in the presence of atmospheric water vapour[5-8]. The basal corners of the cleavage steps represent sites of localized stress concentrations[9]. The stresses at these sites can be intensified by the pervasive thermal stresses present in the sample, arising from its cooling history. Polar atmospheric water molecules preferentially attack the glass at the sites of greatest stress concentration, causing stress corrosion cracks to develop and propagate[6-8].

Several years ago, Wiederhorn[5] drew attention to the potential importance of stress corrosion on the long-term performance of nuclear-waste glasses, but the significance of his contribution has been largely ignored. Nevertheless, if HLW glass experienced extensive stress-corrosion cracking over an extended period after burial in a geological repository, the effective area exposed to leaching would be greatly increased and the survival time of the glass correspondingly decreased. In these essentially unpredictable circumstances, the conventional methods of predicting long-term performance of glasses on the basis of short-term measurements of average leach rates of laboratory-prepared glasses with constant surface area, would be decidedly inadequate.

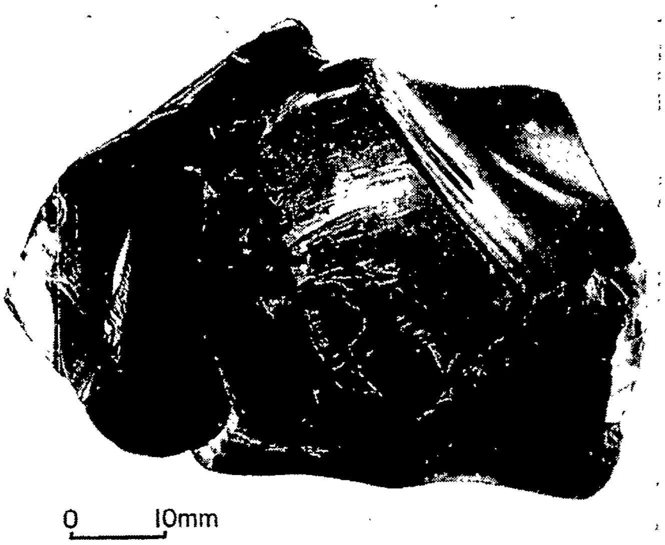

Fig. 1 Sample of borosilicate glass containing ~25% of simulated high-level US defence wastes, produced by in-canister melting at the Savannah River Laboratory of the US Department of Energy. Note the presence of abundant cleavage steps on some of the surfaces.

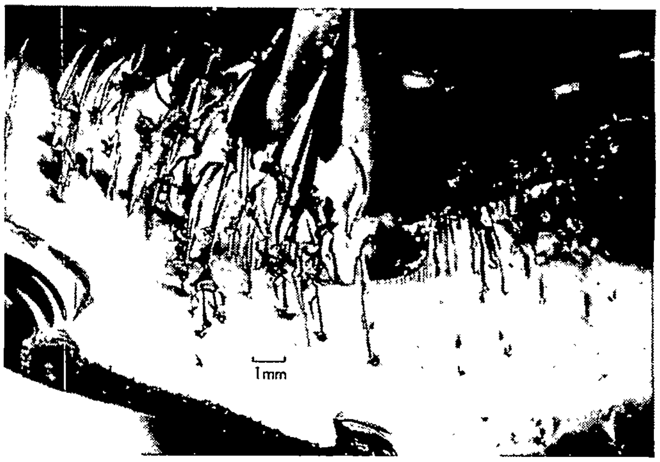

Fig. 2 Glass surface shows complex cleavage steps, mostly originating at crystalline inclusions. Some of these steps represent the outcrops of planar fractures containing iridescent air films.

Studies of polished and thin sections showed that the crystalline inclusions consisted of small spinels (mostly 30–100 μm), commonly sheathed by laths of acmitic pyroxene. The glass immediately surrounding the larger spinel crystals is sometimes observed to be optically anisotropic. This feature is apparently caused by stresses arising from differential thermal expansion coefficients of glass and crystals during cooling.

Samples of glass (dimensions, 1–3 cm) were removed from the interior of the specimen and polished to yield planar surfaces, free of any cracks. The samples were then placed in closed Teflon containers and immersed in 20 ml of deionized water at 95 °C for 25 days. At the conclusions of these treatments, the glasses were covered by loosely adhering iridescent films of hydrous oxides. These were easily removed by a minimal degree of polishing. The underlying surfaces of the glasses displayed several interesting features (Fig. 3).

The glass immediately surrounding the spinel crystals was selectively removed by leaching so that the spinels were surrounded by deep pits (Fig. 3*a*). We have already noted that the glass immediately next to some of the spinels is anisotropic, indicative of localized stress. The formation of pits around the spinels is believed to be caused by the higher intrinsic leachability of stressed regions. The samples also displayed systems of intersecting grooves which commonly radiated from, and linked spinel crystals. It seems possible that the development and location of these grooves is determined by the interaction of localized stress fields surrounding spinels and the pervasive state of thermally-induced stress which exists within the glass.

The fact that simple leaching of the smooth surfaces of a typical borosilicate glass causes the rapid development of grooves and pits has important implications for the long term behaviour of these glasses. As noted above, the glass is characterized by a pervasive residual thermal stress. The present experiments show that in the presence of water, grooves and pits develop quite rapidly. The effect of a tensile or shear stress of thermal origin will be to magnify the local stress intensity at the bases of the grooves or pits by a factor proportional to $1/\sqrt{R}$ where R is the local radius of curvature[7]. Thus, the bases of grooves and pits will dissolve more rapidly than plane surfaces and these features will propagate into the interior of the glass much faster than the average rate of surface dissolution. This process of inhomogeneous dissolution may lead ultimately to disintegration of the glass, with a large increase in the effective surface area which can be exposed to the attack of groundwater.

The development of grooves as seen in Fig. 3 seems to reflect a form of stress corrosion. These features may propagate steadily into the interior of the glass through preferential dissolution at their tips as discussed above. Alternatively, if the stress intensity within the glass should exceed a critical limit, they are likely to propagate catastrophically in stress corrosion cracks. In regions subjected to tensile stress, Si-O bonds are stretched and preferentially attacked by polar water molecules which become inserted between the silicon and oxygen atoms in the Si-O-Si glass network. In consequence, Si-O bonds are broken and replaced by Si-O-H|H-O-Si groupings where the vertical bar represents a rupture. This causes a crack to propagate inwards[8,10]. The propagation distance is primarily controlled by the stress intensity at the tip of the crack. With an isolated stress centre, the stress intensity decreases with distance and crack growth is ultimately halted. If, however, the entire specimen is also subjected to an overall tensile or shear stress exceeding the critical limit, the crack will propagate through the entire specimen. Alternatively, if there is a high spatial density of stress centres (see below), their localized crack propagation envelopes may intersect, with catastrophic consequences.

After burial in geological repositories, nuclear waste glasses are likely to be subject to additional critical stresses arising from the effects of radiation damage on included crystalline phases. Borosilicate glasses produced on a large scale for HLW immobilization frequently contain a few per cent of dispersed crystalline phases, including metallic alloys, a fluorite-type phase $Ce^{4+},REE^{3+}O_{2-x}$, spinels, silicates and molybdates[1,2] (where REE is the rare-earth element). The volume expansions exhibited by some of these crystalline phases after strong irradiation from α particles may be as high as several per cent, whereas glass does not usually expand beyond 1% (ref. 1). Localized stresses will be induced in the glass surrounding the damaged crystals. These stresses may greatly exceed the thermally-induced stresses around the spinel crystals in the present glass, which are caused by differential volume changes <1%.

In these circumstances, it seems that localized stresses around many of the larger (for example, ~50 μm) crystalline phases could eventually exceed the critical levels required for the initiation of stress corrosion cracking on surfaces, which are in contact with groundwater, or even with atmospheric water vapour. The capacity of nuclear waste glasses to withstand ultimate disintegration because of these factors is open to question.

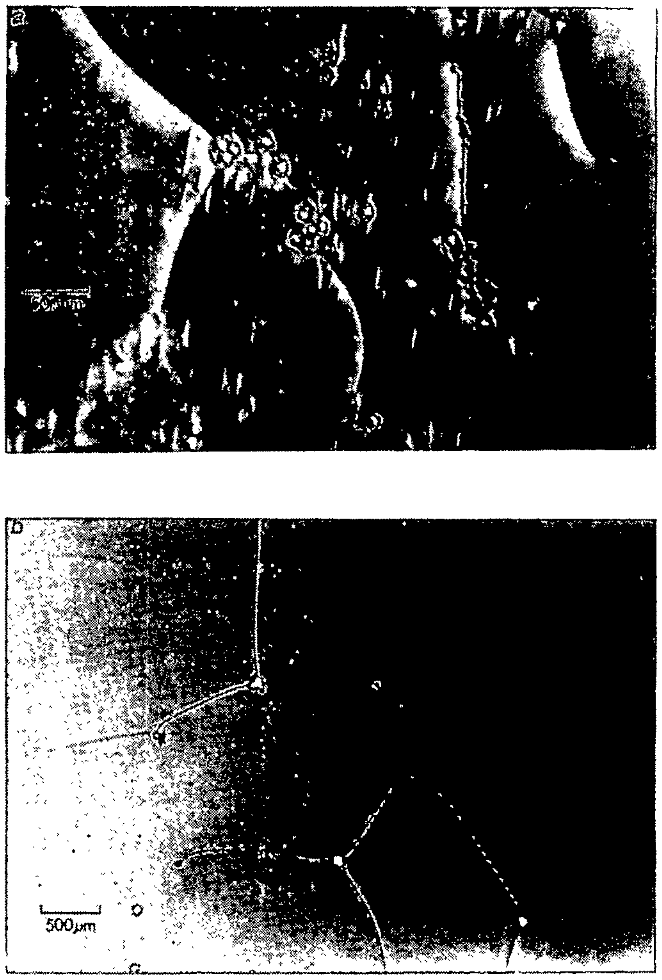

Fig. 3 Originally planar polished surfaces of glass sample from the interior of specimen after leaching. In *a*, spinel crystals now sit in deep pits formed by selective leaching of stressed envelopes. Note development of grooves associated with spinel crystals. These are believed to represent incipient stress corrosion cracking.

The considerations advanced above suggest that susceptibility to stress corrosion cracking should be an important criterion in the evaluation and selection of wasteforms for high level nuclear waste.

We thank Dr B. Lawn of the US Bureau of Standards for discussion and constructive criticism. The investigation was partially supported by a grant provided by the National Energy Development and Demonstration Program of the Commonwealth Department of Resources and Energy.

A novel ignition device for the internal combustion engine

A. J. J. Lee & F. J. Weinberg

Department of Chemical Engineering and Chemical Technology,
Imperial College of Science and Technology, London SW7 2BY, UK

Although the recent rapid proliferation of research into plasma jet ignition[1–16] has partly been prompted by the requirements of continuous combustion and pollutant removal[17–25], the main motive has been to extend the lean operability limit of the internal combustion engine. This trend to leaner mixtures has been stimulated by the need to improve engine emission characteristics and efficiencies. Because optimum conditions occur near the lean misfire limit, a plug providing increased rates of flame propagation and more effective and reliable ignition has been sought; pulsed plasma jets offer much promise but use too much power. In these devices, the igniting jet is generated by explosive gas expulsion through an orifice, engendered by a short-duration arc discharge to which the plasma medium is exposed while confined by the walls of a cavity within the plug. Such plasma jets, and particularly those fed with specific plasma media, have proved capable of extending the flammable fuel–air mixture range both at the fuel lean and at the rich limit, and increase the speed at which flames propagate following ignition. This is thought to be due to the generation of turbulence and free radicals. We report here the development and testing of an ignition plug based on two sparks at the extremities of an internal cavity. This design combines much of the effectiveness of a plasma jet with the small power consumption, and consequently low rates of wear, of a conventional sparking plug.

From the point of view of practical applicability, plasma jets suffer from a major shortcoming; they use appreciably larger amounts of energy than do conventional automobile ignition systems. This results not only in increased consumption of electrical power but also in much greater rates of electrode wear. The former may be improved by redesigning the electrical supply system for greater efficiency, as the small proportion of the total energy which eventually reaches the jet[10] is not inordinately larger than conventional spark energies. The latter, however, restricts plasma plug life to, at best, tens of hours. Thus we set out to design and test an ignition plug[26] which would combine some of the essential features of plasma jet ignition with the energy requirements of a conventional spark plug.

The essential features seem to be the production of a high-velocity gas jet which contains at least some regions or pockets of high-temperature gas within which active species, such as free radicals, reside. The spark channel itself, being at an extremely high temperature, is a sufficient source of the latter—without requiring the dissipation of a lot of energy in its creation. The main energy requirement in plasma jets (apart from losses due to the large currents used) seems to be associated with the generation and expulsion of the jet. If this could be contrived by drawing on the large amount of chemical energy in the fuel rather than on the electrical input, the major need for large amounts of electrical power would be removed. The plug design[26] in Fig. 1 achieves this aim as follows. Of the two sparks in series, the one at the base of the cavity is intended to ignite the flammable mixture compressed into the cavity by the advancing piston. The spark channel across the mouth of the cavity then rides on top of the ejected column of gas. For very lean mixtures, or fuels that are particularly difficult to ignite, small amounts of fuel or other substances which will promote reaction within the cavity may be introduced. Simple methods for providing the cavity with minute flows of gas, wetting it with small amounts of liquid fuel or furnishing it with solid hydride inserts have been developed in research on plasma jets[8,9,11,13].

Table 1 Extension of incendivity limits, both spark gaps broken down

Cavity parameters Length (mm)	Volume (mm^3)	Contents	% Limit extension Lower	Upper
10	31.4	Test mixture	9.5	2.7
10	31.4	Oxygen mixture	14	56

Table 2 Increase of flame speed

Cavity parameters Length (mm)	Volume (mm^3)	Contents	% Improvement Top spark only	Both sparks
1	3.14	Test mixture	47	64
2	6.28	Test mixture	48	59
4	12.6	Test mixture	42	63
7	22.0	Test mixture	55	74
10	31.4	Test mixture	45	80
1	3.14	Oxygen mixture	137	162
2	6.28	Oxygen mixture	132	200
4	12.6	Oxygen mixture	253	251
7	22.0	Oxygen mixture	282	270
10	31.4	Oxygen mixture	183	351

There is evidence of jet formation and some gas expulsion through the orifice even in the absence of a flammable mixture in the cavity. With a small cavity, even the small amount of energy that the internal spark imparts to its contents is sufficient to raise the temperature significantly, at least at atmospheric pressures. Thus if the spark energy were uniformly distributed across the 33 mm^3 of the cavity, a doubling in the absolute room temperature would require some 10 mJ. Of course, the energy release from a stoichiometric mixture is almost an order of magnitude higher, even at atmospheric pressure, whilst, at engine pressures, the electrical contribution to the ejection of the jet would be expected to be relatively insignificant.

Practical tests to help elucidate the mechanism included a study of what happens when the two electrode gaps are shorted out in turn. Ignition at the base of the flammable contents of the cavity first ejects reactants into the gas to be ignited and eventually flame, if that has not been quenched within the cavity. Discharge at the upper electrode gap alone corresponds to conventional spark ignition only if the cavity is not filled with a flammable mixture. If flame propagation into the cavity can occur then the spark channel finds itself in a jet of hot products—again unless the flame is quenched. Comparing the incendivity of the device in these various conditions with that of the two-discharge configuration gives much information on quenching and the mechanism by which the igniter functions generally. The quenching criterion is less restrictive in an engine than during tests at atmospheric pressure because quenching distance is inversely proportional to pressure. Quenching distance also decreases with increasing burning velocity and is about 10 times less for a stoichiometric mixture than at the limits of flammability. For this reason a series of experimental tests at atmospheric pressure were conducted with more vigorous flammable mixtures in the cavity to minimize quenching within it and simulate, in this respect, the most extreme engine conditions.

Before any fundamental work to optimize the plug design could be carried out, an opportunity arose to test the ignition device in a Ricardo experimental engine. It spite of the unoptimized cavity geometry, very promising reductions in burn times were obtained. As expected, these were greatest for the initial stages of propagation (8–9% during the first 10% of burn time) but were not inappreciable even when averaged over most of the flame travel (5–6% for 90% burn time).

In view of the difficulties encountered during engine experiments, more academic studies were carried out at atmospheric pressure with an adjustable plug (see Fig. 1*b*). This included provision for the feed of specific media as well as for variable cavity lengths and hence volumes. The most sensitive

measure[9,10,16,21] of incendivity,was found to be the stoichiometry of the leanest and richest mixtures which, when ignited at the centre of a vessel 10 cm square, would propagate flame all the way to the walls at least four times out of five. The other essential parameter is the speed of propagation of the flame. This was determined by measuring the time that the flame took to reach the ionization probe situated as shown in Fig. 2. The total stored energy available from the conventional ignition coil was of the order of 9 mJ.

The results for methane-air mixtures, based on several hundred firings, are listed in Tables 1 and 2. The 'percentage improvement' refers to the decrease in minimum or increase in maximum fuel concentration which could be ignited, or to the increase in flame speed, all compared with the results for a conventional spark plug with a 2-mm gap. 'Test mixture' in the cavity signifies that the feed is the mixture under test in the vessel. 'Oxygen mixture' refers to the feeding into the plug of oxygen bubbled through mixtures of acetone and isopropanol in a saturator. The fastest burning mixtures studied produced stoichiometric conditions within the cavity. The flow in these experiments is minute, $\sim$0.083 cm^3 s^{-1}, which is only sufficient to compensate for diffusion losses through the orifice and can have no appreciable effect on the composition of the test mixtures[16]; this was stoichiometric methane-air for all the burning velocity measurements.

The lower and upper limit determinations were obtained using a plug without the extended electrodes shown in Fig. 1*b*, to avoid the quenching which these surfaces seem to induce at the lower limit. The spark duration was of the order of 1 ms. When it was reduced to 0.1 ms, no extension of limits of incendivity was observed, except for the oxygen mixtures, presumably because the spark at the mouth of the cavity expired before the jetting action became effective. Results with the bottom spark only are not listed in Table 2 because no ignition was achieved with the test mixture in the cavity, whilst ignition occurred only sporadically and irreproducibly with the oxygen mixture. When ignition did occur, however, burn times were virtually the same as for the two-spark system.

The new ignition device can extend the limits of incendivity and the rates of flame propagation—both sets of results compare favourably with the performance of high-energy (several joules stored) plasma jets (see refs 9, 16). The very large extension of the rich flammability limit for the more vigorously burning plasma media agrees with the plasma jet studies of ref. 16 and, by analogy, may be expected to be accompanied by large reductions of soot generation. The two-spark system consistently achieves large improvements over conventional sparking plugs. When the cavity is filled with the stoichiometric oxygen-fuel mixture, ignition by the top spark alone can produce very similar results—at least for cavities of intermediate lengths. The same is true for ignition by the bottom spark alone, though this is erratic and often does not occur at all. These results make good sense because, in the case of ignition with the top spark, propagation into the cavity results in the expulsion of a hot product jet immediately; in contradistinction to the spark at the base of the cavity, which will eject cold reactants until the flame reaches the top of the cavity-if it is not quenched before then. Unless a second spark is present at the top to ignite this cold reactant jet, the generation of turbulence (cold) is the most the jet can achieve. As the gas expansion due to combustion has been dissipated by the time that the flame reaches the top of the cavity, following ignition at the base alone, (all the jet velocities are readily calculable in terms of burning velocity and flame area) this type of 'torch ignition' would only occur when unquenched flame is ejected.

It is not possible to simulate cavity quenching in engine conditions accurately by feeding the plug any specific mixture, if only because a practical igniter has to cope with various throttle openings. The stoichiometric fuel-oxygen mixture used here was designed to represent one extreme, with burning velocities in excess of any that are likely to be obtained in an engine. It may be that it is only in such extreme conditions that either of the single spark systems generates a jet approaching the performance of the double spark configuration. The effectiveness of the plug in various conditions will also depend on the cavity diameter and orifice geometry, and further studies of the influence of these parameters are in progress. However, although single sparks at the top or the bottom of the cavity can sometimes produce considerable improvements over conventional sparking plugs, the double spark system produces large improvements consistently. It offers the advantages which have been claimed for plasma ignition without drawing any more electrical power than conventional spark plugs currently used in internal combustion engines.

We thank Mr. E. L. Marshall (BP Research Centre, Sunbury) for engine tests, Dr Ivan Vince who participated in some of the experimental work and the Wolfson Foundation for financial support to A.J.J.L.

Climatic impact of explosive volcanic eruptions

P. M. Kelly & C. B. Sear

Climatic Research Unit, School of Environmental Sciences,
University of East Anglia, Norwich NR4 7TJ, UK

Major explosive volcanic eruptions inject ash and gas into the upper atmosphere, producing aerosol layers which can affect the global energy balance and climate[1]. Empirical studies have shown that major eruptions can produce a decrease in surface air temperature of up to a few tenths of a degree Celsius over the Northern Hemisphere land masses and that the effects may last for 2 or 3 yr (refs 2–4). This temperature decrease has been simulated by numerical models using realistic estimates of the nature of the aerosol cloud[1]. Previous empirical studies of volcanic effects have examined fluctuations in monthly, seasonal or annual climate data, but generally only at a frequency of one observation per year. This has rendered determination of the timing of the onset of effects during the first year impossible. Using continuous monthly surface air temperature for the Northern Hemisphere land masses, we resolve the month-by-month development and decay of the initial climatic impact. In the case of Northern Hemisphere eruptions, abrupt cooling occurs during the first two to three months, which is more rapid than previously assumed.

Dates of major eruptions during the study period, 1881–1980, were extracted from records of volcanic activity based on geological evidence[5,6], on anecdotal, geological and other evidence[7–10] and on conductivity (acidity) profiles from ice cores[11]. Nine events were selected for study (Table 1). The selection criteria are summarized in the notes accompanying Table 1. As this study is concerned primarily with the initial climatic impact, the volcanic events were stratified into Northern Hemisphere and Southern Hemisphere samples. During the first few months of its lifetime, a volcanic cloud will be restricted to the hemisphere of injection, even in the case of low-latitude volcanoes[12]. Two superposed epoch analyses were undertaken to define the Northern Hemisphere temperature response to the Northern Hemisphere and Southern Hemisphere eruptions. We used a recent compilation of monthly surface air temperatures[13] interpolated onto a regular grid from station observations before averaging over the Northern Hemisphere.

Superposed epoch analysis is commonly used in studies of the effects of volcanic activity on climate[2–4]. Taking the date of each eruption event as month zero, temperature data for succeeding months were averaged to produce the composite volcanic signals seen in Fig. 1. The value for month zero in the

Table 1 Volcanic events selected for study

Several factors determine the climatic significance of a volcanic eruption. The explosivity of an eruption affects the height of injection and, in particular, whether or not the dust and gas enters the stratosphere where residence times are much longer than in the lower atmosphere. The dust ejected (which is largely silicate ash) affects the energy balance in the initial stages of the development of the volcanic cloud. The amount of sulphur is, however, considered to be a more critical measure of climatic significance[1]. The initial injection of sulphur gases is rapidly transformed into sulphate aerosols (secondary aerosol production) which have a greater effect on the energy balance and a longer residence time than the particulate injection.

All volcanic histories are prone to error because of the rudimentary nature of the historical data available and can only provide a crude classification of eruption size and climatic significance[9]. An objective synthesis of the available information has, therefore, been used to identify the events most likely to be of climatic importance. Well-dated events with a VEI of ⩾5 and/or a DVI of ⩾300 were selected.

* Not included in the superposed epoch analysis as effects are likely to be obscured by eruptions earlier in 1902.

† VEI, Volcanic explosivity index[5,6]; DVI, dust veil index[7,8,10], not weighted by extent of veil; acidity, global fallout (10^6 tons)[11]. Acidity estimates are not available for many of the eruptions.

Table 2 Monthly standard deviations (°C) of the Northern Hemisphere average surface air temperature data (1881–1980)

January	February	March	April	May	June
0.64	0.54	0.42	0.35	0.31	0.28
July	**August**	**September**	**October**	**November**	**December**
0.23	0.25	0.27	0.39	0.44	0.50

Northern Hemisphere composite shown in Fig. 1 corresponds to the average over the eruption months listed in Table 1; the value for month 1 is then the average of the temperature data for June 1902, April 1907, July 1912 and April 1956, and so on. The superposition, or compositing, clarifies the volcanic signal by averaging out features not common to the individual events. These are, presumably, caused by non-volcanic factors and can be considered to be noise.

To avoid biasing the results towards the winter months when the variability is greatest (Table 2), the data were standardized before compositing. Each monthly temperature value was divided by the appropriate long-term (100-yr) standard deviation after subtraction of the long-term monthly mean. We have repeated the analysis using unstandardized data and the general conclusions are not affected. To reveal the short-term response and avoid the effects of longer-term climatic changes, the data were then expressed as departures from the prevailing temperature level defined by the 12-month average for the period up to the eruption date (that is, month −12 to month −1). Use of longer averaging periods, of up to 5 yr, made little difference to the results.

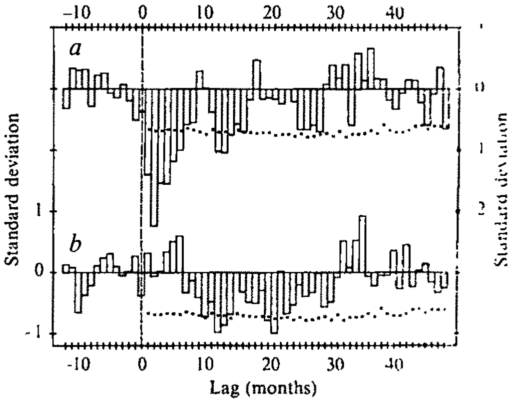

Fig. 1 Superposed epoch analyses of standardized monthly Northern Hemisphere surface air temperatures for the Northern Hemisphere eruption sample (*a*) and the Southern Hemisphere eruption sample (*b*). The data are expressed as deviations from prevailing temperature levels defined by the 12-month average for the period up to but not including the eruption date (month zero). To convert standard deviation units to °C, use Table 2. The near-horizontal line of dots indicates the one-tailed 5% significance level based on a Monte Carlo simulation. It should be noted that these data are largely representative of conditions over the land masses of the hemisphere as few data are available for ocean areas at present. Most of the eruptions studied took place during the early decades of the record for which the spatial coverage of the data is best over middle to high latitudes.

Statistical significance was tested using a Monte Carlo technique[14], so implicit account was taken of the particular statistical characteristics of the data under analysis (for example, systematic fluctuations caused by non-volcanic factors[15]). Values for months 1–48 were calculated as above using 1,000 sets of four randomly selected 'eruption' dates. The distribution of the resulting samples of 1,000 values was used to determine 5% significance levels separately for each of the 48 months. A one-tailed significance test was used, as it is generally accepted that surface cooling is the probable climatic effect[1].

The composite temperature departure sequences for the two samples are shown in Fig. 1. The Northern Hemisphere composite shows a marked response: a rapid decrease in temperature following month zero, with maximum cooling in month 2, then a slow recovery over the next couple of years. Temperatures return to the pre-eruption level during the third year. The maximum depression is about 2.2 s.d. corresponding to a cooling of ~1.4 °C in January and 0.5 °C in July. Individual departures during the first few months are clearly significant at the 5% level. The cumulative probability of the occurrence of a sequence of departures significant at the 5% level is, of course, extremely low. Statistically significant temperature depressions occur in all but six of the first 16 months and only three positive values occur during the first 28 months. The average depression over the first 12 months is between 0.3 and 0.4 °C depending on the month of the eruption. This agrees well with the results of previous analyses[1-4]. The duration of statistically significant effects is around 18 months, although cooling is still apparent through to the early stages of the third year.

The Southern Hemisphere composite exhibits a similar, but delayed, signal. As we are now considering the effects of Southern Hemisphere eruptions on Northern Hemisphere climate, the delay is to be expected. Persistent cooling is first apparent about month 7 and is strongest during year 2. Depending on the time of year, the maximum cooling in any one month ranges between 0.2 and 0.6 °C and the average cooling during year 2 is ~0.2 °C, rather less than is often cited in the cases of Krakatau and Agung. The termination of appreciable effects at the beginning of the third year is similar to that seen in the Northern Hemisphere composite.

The similarity of the signal revealed by the two independent samples, allowing for the delay in the case of Southern Hemisphere events, strongly supports the reality of the volcanic effect. Nevertheless, there is a need for further verification by repeating the analysis for earlier eruptions and on a Southern Hemisphere temperature average. At present, however, suitable data are not available.

The composite volcanic signals seen in Fig. 1 are statistical generalizations and their applicability to individual events is not necessarily straightforward because of the background climate variability or noise. Temperature departures following the individual volcanic events are shown in Figs 2 and 3. With the composites from Fig. 1 in mind, the outline of the volcanic signal can be seen in most of these sequences. The notable exception is the case of Tarawera. Interestingly, the magnitude of the maximum response, in terms of standard deviation units, is similar in all the individual sequences (except that of Tarawera) although the character and size of the associated stratospheric injections differed. The apparent duration of the climate response does, however, vary from event to event, although the point where the volcanic signal becomes indistinguishable from the background noise is difficult to determine.

The most striking feature of our results is the speed of the climate system's response. Contrary to general belief, the maximum impact occurs when the volcanic cloud is far from being hemispherically distributed. The time scale of the development of the aerosol cloud produced by the eruptions of El Chichón, Mexico, in April 1982[16] is relevant here. Satellite observations[12] of the stratospheric injection have shown that the aerosol cloud at 27 km reached maximum density in late May 1982 as particle growth rates were first balanced and then exceeded by sedimentation losses. The total mass of sulphate above 20 km reached a maximum about 15 weeks after the eruption[17]. Modelling of the chemistry involved suggests a similar 2-5-month gas-to-particle transformation time with maximum optical depths in lower northern latitudes occurring during summer 1982[18]. By the beginning of June 1982, the El Chichón aerosol cloud was homogeneous and circumglobal in longitudinal extent but limited in latitudinal span[12]. Turco *et al.*[19], modelling the net effect on hemispherically averaged vertical optical depth, find maximum departures occurring 1-3 months after the eruption, in agreement with our results. (Unfortunately, the exceptional warmth of 1981[13] and the onset of cooling in early 1982, before the El Chichón eruptions, renders identification of the actual surface air temperature response difficult[20].)

Nevertheless, it is surprising that surface temperatures, even over land, should respond so quickly to the volcanic forcing with little, if any, delay produced by the thermal inertia of the climate system. The mechanism whereby a localized disturbance in the energy balance can produce a swift response in surface air temperature of hemispheric significance (although not necessarily hemispheric extent) warrants further investigation. As Ellsaesser has noted[15], empirical studies concerning volcanic effects on climate tend to raise as many, if not more, questions than they answer. This is symptomatic of many studies of the causes of climatic change and is an almost inevitable byproduct of limited data availability and small sample size.

The strength of the immediate temperature response to volcanic injections revealed by our analysis may result in a limited predictive ability, and the accurate determination of the volcanic signal is relevant to the prompt detection of the climatic effects of increasing levels of atmospheric carbon dioxide[21]. We believe, however, that the major significance of this work lies in the fact that it challenges commonly held beliefs concerning the response time and the sensitivity of the climate system to external forcing.

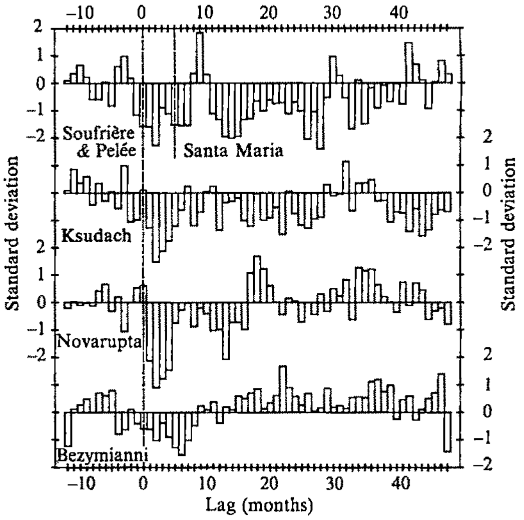

Fig. 2 Individual sequences of standardized monthly Northern Hemisphere temperatures following the eruption dates in the Northern Hemisphere sample (see Table 1). The data are expressed as deviations from prevailing temperature levels defined by the 12-month average for the period up to but not including the eruption date (month zero). To convert standard deviation units to °C, use Table 2.

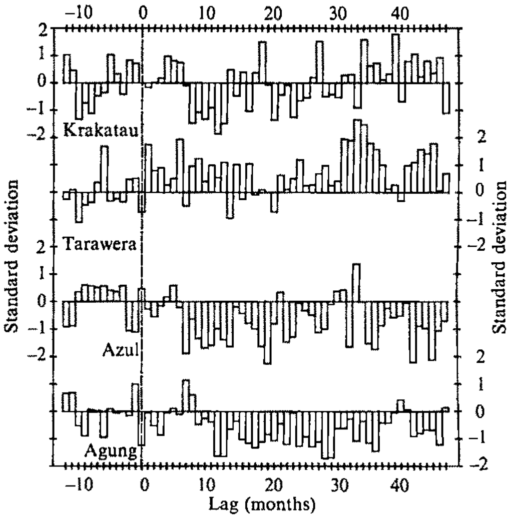

Fig. 3 Individual sequences of standardized monthly Northern Hemisphere temperatures following the eruption dates in the Southern Hemisphere sample (see Table 1). The data are expressed as deviations from prevailing temperature levels defined by the 12-month average for the period up to but not including the eruption date (month zero). To convert standard deviation units to °C, use Table 2.

Our results provide empirical support for the short response time suggested by recent attempts to simulate the climatic effects of a nuclear exchange[19,22].

Nd–Sr isotopic and REE constraints on the genesis of hydrothermal manganese crusts in the Galapagos

N. Clauer*, P. Stille*, C. Bonnot-Courtois† & W. S. Moore‡

Manganese oxide crusts from the Galapagos spreading centre, interpreted to be of hydrothermal origin, have Nd isotopic compositions and rare-earth element (REE) concentrations that approach seawater values as the age increases. Numerous authors[1,2] have cited hydrothermal processes along the mid-oceanic ridges to explain the composition of 'metalliferous' sediments. Other authors believe that these sediments, whether now located on a ridge axis or in some deep, were derived from hydrothermal activity near ridges and were modified during removal from these ridges[3–6]. Nd and Sr isotopic compositions as well as concentrations of REE and Cu, Ni and Co in hydrothermal Mn crusts of different ages from the Galapagos spreading area were determined to provide new information regarding the problem of the alteration behaviour with time of oceanic sediments. Our data suggest that hydrothermal crusts react with seawater and ultimately acquire the trace-element characteristics of hydrogeneous crusts.

During a 1972 oceanographic cruise to the Galapagos spreading axis[7], dredging in the axial valley recovered a 2–4 cm thick Mn crust (station D6) consisting of a surface grey-banded zone covering a dark, friable zone. The latter material is todorokite, whereas the former consists of a mixture of todorokite and birnesite. The basement age is 0.3 Myr as estimated from magnetic anomalies.

At a second station (D9) located on a ridge about 25 km north-east of D6, fragments of another manganese oxide crust were also recovered on a 2.4 Myr old basement. This crust consists of a dark, iron-stained, 2–4-mm thick surface zone covering 4–6 cm of massive, grey material. The outer layer is amorphous material, and the underlying 4–6 cm is a mixture of todorokite and birnesite. Samples analysed are identified in Table 1.

Previous studies[7] showed that the outer layer of the D9 crust was hydrogeneous, but that the 0.3-Myr old D6 and the 2.4-Myr old D9 crusts are of hydrothermal origin. This conclusion is supported by the high accumulation rates measured by ^{230}Th/^{234}U dating of the Mn crusts, as well as by the young basement age determined by magnetic anomalies. Thus the growth rate for the D6 crust is of the order of 1–2 mm kyr^{-1}, 1,000 times faster than the growth rate of hydrogeneous Mn deposits.

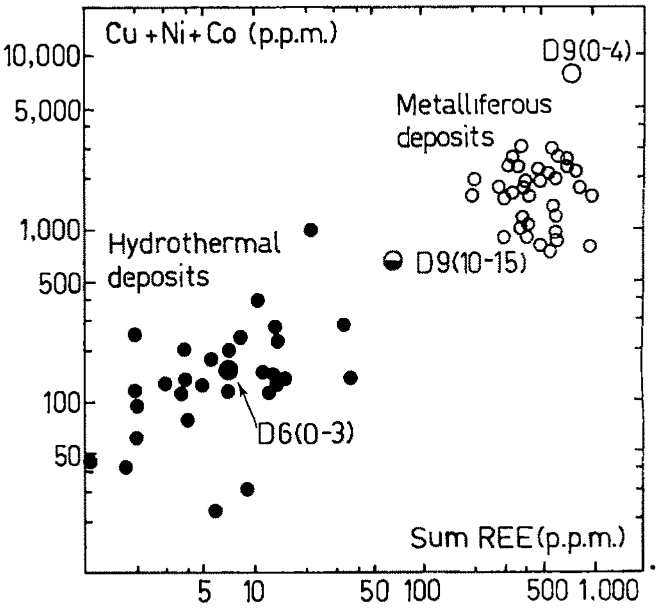

Fig. 1 Correlation between REE and Cu + Ni + Co concentrations in hydrothermal deposits and metalliferous sedimentary deposits. Data, characterized by smaller open and filled circles, are from ref. 10 corresponding to hydrothermal and metalliferous material from FAMOUS, Galapagos, Cyprus, Leg 54, Bauer deep, Marquesas zone, North Pacific[4,19–22].

A comparison of Cu + Ni + Co concentrations with REE concentrations (Fig. 1), provides a means of differentiating and characterizing hydrothermal and hydrogeneous Mn deposits. Hydrothermal deposits have REE and Cu, Ni and Co concentrations that are distinctly lower than those of hydrogeneous deposits. The data for the hydrothermal section of D9 fall in a region of the diagram that is intermediate between those of hydrogeneous deposits, here typified by its own outer coating, and those of hydrothermal deposits typified by the younger D6 crust.

In Fig. 2, the shale-normalized distribution of REEs[8] in the hydrothermally-formed D6 crust is quite similar to those of other hydrothermal deposits from the Galapagos[9] and from the FAMOUS area[10]. The crust shows a weak negative Ce anomaly and a slight increase in the heavy rare-earth elements (HREEs). The REE patterns of hydrothermally-formed parts of the D9 crust are significantly different from those of D6. Especially striking is the strong Ce anomaly and the marked similarity of the REE patterns to that of Pacific Ocean water and of authigenic marine sediments. The outer hydrogeneous layer of the same crust contains very high REE concentrations of about 765 p.p.m.; again the pattern shows a slight enrichment in the HREEs, but the negative Ce anomaly is less developed than in the hydrothermal portion.

The Sr isotopic ratios measured on 12 samples of the D6 and D9 crusts are remarkably constant. The average value is 0.70906 ± 4 (2σ mean) and thus agrees very well with present seawater Sr isotopic composition[11]. The Sr isotopic ratio of seawater measured in the hydrogeneous outer coating of D9 was as expected. For the hydrothermally-formed parts of the crust, however, we suggest either that the Sr originally had seawater-like ratios or more probably that exchanges with seawater occurred after the crust was formed.

Albarede *et al.*[12] measured the Sr isotopic compositions of hydrothermal waters and deposits from the East Pacific Rise

(EPR) and showed that the hydrothermal system may be basically handled as a two component system in which endmembers are (1) the ambient seawater, and (2) a hot hydrothermal solution with $^{87}Sr/^{86}Sr$ ratio of 0.703, close to, but significantly higher than, the Sr isotopic ratio of the surrounding fresh basalts. Similar observations were made by Vidal and Clauer[13] in their combined Pb–Sr isotopic study of basalts and sulphides from the EPR. They found that the Sr isotopic compositions of the hydrothermally-formed sulphides were intermediate between those of basalt and seawater.

Based on these studies and the strong evidence for the hydrothermal origin of the D6 and lower parts of the D9 crusts, we suggest that originally both seawater and hydrothermal Sr were incorporated in the Mn crusts. Later, after a long exposure to seawater, the original Sr isotopic compositions changed to present seawater values.

This suggestion is supported by the Nd isotopic compositions and Nd concentrations obtained on D6 and D9 crusts (Fig. 3). The isotopic composition of hydrothermal water is suggested to be mid-ocean ridge basalt (MORB)-like. The hydrogeneous samples, including the outer coating of the D9 crust, are characterized by high Nd concentrations ranging between 150 and 300 p.p.m. and Nd isotopic compositions that are the same as Pacific ocean water and agree within error limits with those found by Goldstein and O'Nions[14] on the same D9 crust. In addition, the hydrothermal portion of the D9 crust has a seawater Nd isotopic composition, but its Nd concentration is intermediate between the data for the remaining hydrothermal and hydrogeneous Mn crusts. The two hydrothermal samples (HC-1 and D6) have very low Nd concentrations of <2 p.p.m. and Nd isotopic compositions that are higher than the upper limit for Pacific Ocean water. This observation indicates that the Nd in these deposits has a volcanogenic component.

Corliss[15] demonstrated that hydrothermal leaching of submarine basalts could supply all excess REEs in the hydrothermal and hydrogeneous crusts. His geochemical balance calculations further show that the REE concentrations in hydrothermal mineralizing solutions are significantly greater than the concentrations of the seawater reservoir. This is supported by new measurements on high temperature hydrothermal waters from the EPR by Michard *et al.*[16] who demonstrated that REE concentrations in hydrothermal fluids are approximately 1,000 times those of seawater.

Assuming that leaching of basaltic material is the main mechanism which produces excess REE in the hydrothermal solutions and that its Nd isotopic composition and REE distribution was similar to MORB, then ~15–20% of the total Nd in the hydrothermal Mn crust of D6 must have been derived from a magmatic source and 80% from Pacific seawater.

Because of the extremely low REE concentrations in seawater, its mixing with a basalt source in the above-mentioned proportions will still produce a basaltic REE pattern. However, as shown in Fig. 2 only the HREEs in the hydrothermal crust of D6 reflect a basaltic component. The strong light rare-earth element (LREE) depletion, typical for MORB, is not observed. Thus, if hydrothermal leaching of basalts was the main mechanism which accumulates REEs in the hydrothermal solutions it did not fractionate the HREE but it enriched the LREE relative to the HREE. This suggestion is in good agreement with the geochemical mass balance calculations of Corliss[15], which demonstrate that in hydrothermal leaching of basalts three times more Ce than Sm accumulates in the solutions. It also agrees with the statement of Michard *et al.*[16] who observed a large enrichment of LREE in hydrothermal waters relative to seawater.

The 2-Myr older hydrothermal portion of the D9 crust was possibly formed in different conditions than that of the D6 crust. A larger seawater or even detrital component might be responsible for the significantly lower Nd isotopic compositions and the REE concentrations that are higher than usual for hydrothermal deposits.

The strong similarity in REE patterns to those of ocean water might indicate that seawater rather than detrital sediments was responsible for modifying the chemical characteristics of these crusts with time. We, therefore, suggest that the REE patterns of D9 reflect mixing between a hydrothermal and a seawater pattern. The theoretical mixing REE pattern is shown in Fig. 2. If our suggestion is correct and the crust originally had a REE pattern similar to that of the 2 Myr younger D6 crust, then the material must have undergone extensive REE exchange with seawater, possibly by a diffusion process[17,18]. Such post-depositional processes seem to alter significantly the composition of elements and to erase the original hydrothermal signature.

We thank J. Abrecht, P. J. Patchett and J. R. O'Neil for helpful discussions and English corrections. This work was funded by a grant from the Swiss National Science Foundation to P.S.

Efficiency of petroleum expulsion from shale source rocks

D. Leythaeuser, M. Radke & R. G. Schaefer

Institute for Petroleum and Organic Geochemistry (ICH-5),
KFA-Jülich, PO Box 1913, D-5170 Jülich, FRG

The limited data available on the mechanism and the efficiency of the processes by which petroleum is expelled in the subsurface from source rocks into adjacent reservoir rocks are mostly qualitative[1,2]. We present here material balance-type comparisons of sample series extending from the centre portions of two adjacent hydrocarbon source rock units towards their outer edges[3], which enable expulsion efficiencies to be determined. In certain parts of the shale the expulsion efficiencies for total extract and its saturated and aromatic hydrocarbon fractions, have much higher values than previously thought (reaching up to 80% for the total extract) which increase towards possible secondary migration avenues. The expulsion is associated with fractionation effects, such as those based on polarity differences. Also, expulsion efficiencies were found to be related to the degree of hydrocarbon saturation of the pore system: they are higher for a rich, oil-prone source rock unit compared with a poorer quality one, which had generated less hydrocarbons.

Using geochemical techniques described elsewhere[4,5] 15 samples of conventional cores were analysed from a ~30-m thick organic matter-rich shale interval in the Kökelsumer Heide no. 1 well penetrating Upper Carboniferous coal-bearing strata in the northern Ruhr district, FRG. From the variation of its organic carbon content and kerogen composition[6] (as defined by the hydrogen index HI, ref. 7), this shale could be subdivided

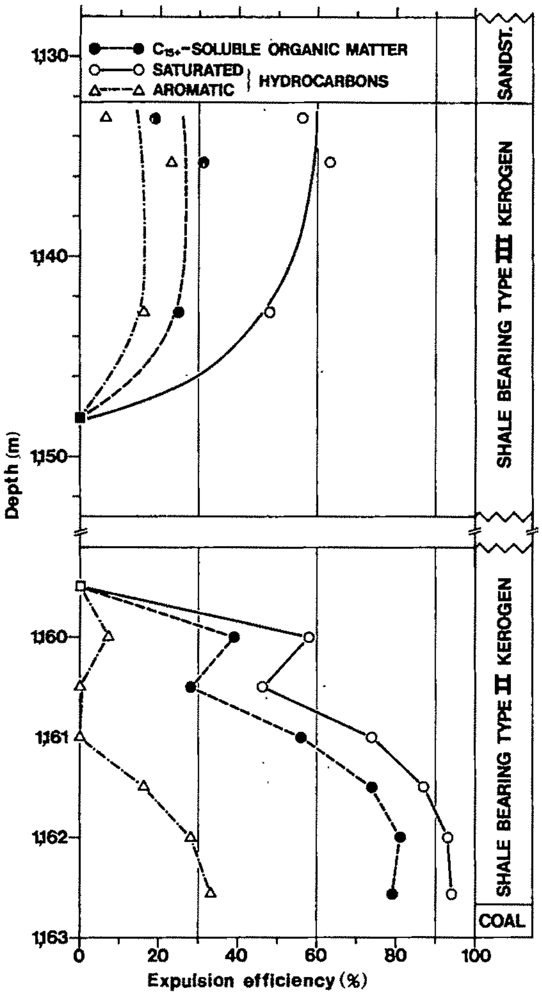

Fig. 1 Efficiency of expulsion of C_{15+}-soluble organic matter and saturated and aromatic hydrocarbons plotted against depth for the upper and lower depletion intervals of shale unit 1,132.5–1,162.6 m in the corehole Kökelsumer Heide No. 1, Ruhr district, FRG. The calculation of expulsion efficiencies[10,11] was based on the assumption that samples 1,148.1 m and 1,159.5 m have the hydrocarbon concentrations which resemble most closely those generated *in situ* (unmodified) for the upper and lower shale interval respectively.

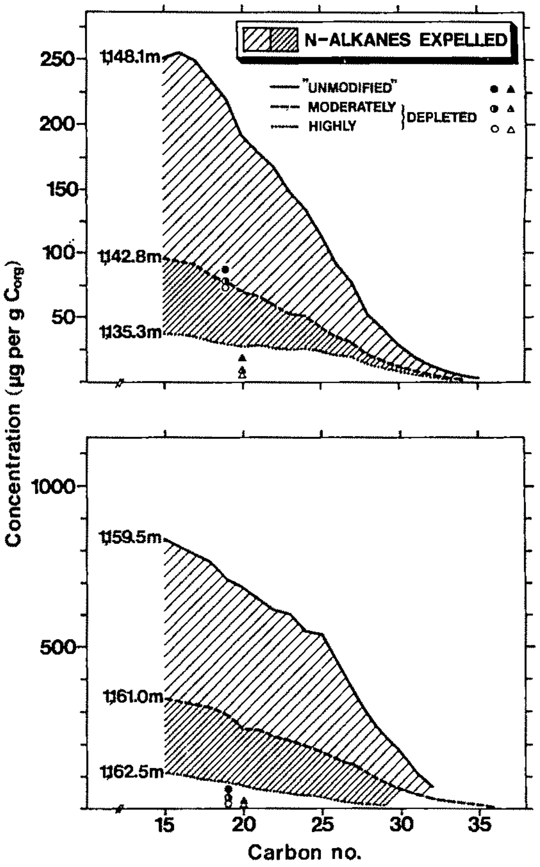

Fig. 2 Comparison of the absolute amounts of individual normal and isoprenoid alkanes (µg per g C_{org}) based on quantitative evaluation of the gas chromatograms for selected samples from the upper (1,148.1, 1,142.8 and 1,135.3 m) and lower depletion intervals (1,159.5, 1,161.0 and 1,162.5 m) of the shale unit shown in Fig. 1. The designation of samples as 'unmodified', 'moderately' and 'highly depleted' is explained in the text. Concentration differences between the three samples from each depletion zone represent hydrocarbon mixtures expelled from the indicated interval during primary migration. Circles, pristane; triangles, phytane.

into two intervals (Fig. 1, right hand column):

(1) From 1,132.5 to 1,158.0 m a medium grey shale with modest organic carbon content (mean, 0.8%) and bearing a hydrogen-lean type III kerogen[8] (mean HI 61.2 mg hydrocarbons per g organic carbon) was penetrated.

(2) From 1,158.0 to 1,162.6 m a black shale of high organic carbon content (mean, 3.9%) and bearing a hydrogen-rich, oil-prone type II kerogen[8] (mean HI, 175 mg per g organic carbon) occurs. Stratigraphically, this interval is the 'Katharina shale', which was deposited during a short marine transgression and directly overlies the Katharina coal seam[9].

Within each of these intervals the kerogen composition remains uniform except for the lowermost two samples of (2) where a high proportion of reworked and oxidized organic matter is thought to have been admixed with the type II kerogen[6]. Formation of petroleum hydrocarbons has advanced in both shales to beyond the peak generation stage as indicated by a maturity level of the organic matter equivalent to 1.1% mean vitrinite reflectance. The qualitative effects of hydrocarbon expulsion from the above-defined source rock intervals have been reported previously[6]. We now concentrate on quantifying some of these expulsion effects.

Samples from the upper and the lower edge of shale interval 1,132.5–1,162.6 m had systematic differences in concentration and composition of extractable hydrocarbons compared with samples from the centre[6]. Using an established concept[10,11] we now attempt to quantify these observations. For this purpose, the samples at 1,148.1 m and 1,159.5 m were assumed to have the hydrocarbon concentrations, which resemble most closely those generated *in situ* (that is, those within each shale unit relatively least affected by expulsion losses). They are referred to as the 'unmodified' samples, although they may also have lost some of their originally-generated hydrocarbons.

The percentage decrease in total extract and extractable hydrocarbons, shown in Fig. 1, for all samples closer to the upper and the lower shale contact respectively are interpreted as reflecting the expulsion efficiency. Over the uppermost 12-m and the lowermost 2.5-m intervals, the expulsion efficiencies for the total extract and its saturated and aromatic hydrocarbon fractions increase strongly towards the outer shale contacts: the edges of the shale have been preferentially depleted by expulsion. At any given depth level within both depleted intervals the expulsion efficiency is highest for the saturated hydrocarbons and lowest for the aromatic hydrocarbons; that of the total extracts is between the two. These trends are more regular in the lower depletion interval, where expulsion efficiencies increase within a narrow interval of only 2.5 m for the total extract to almost 90%, and for the saturated and aromatic hydrocarbons up to 94 and 33% respectively. The drainage avenue into which the expelled hydrocarbons were transported is obvious for the upper depletion zone (the overlying sandstone), while it is not as clear for the lower one. Several thin

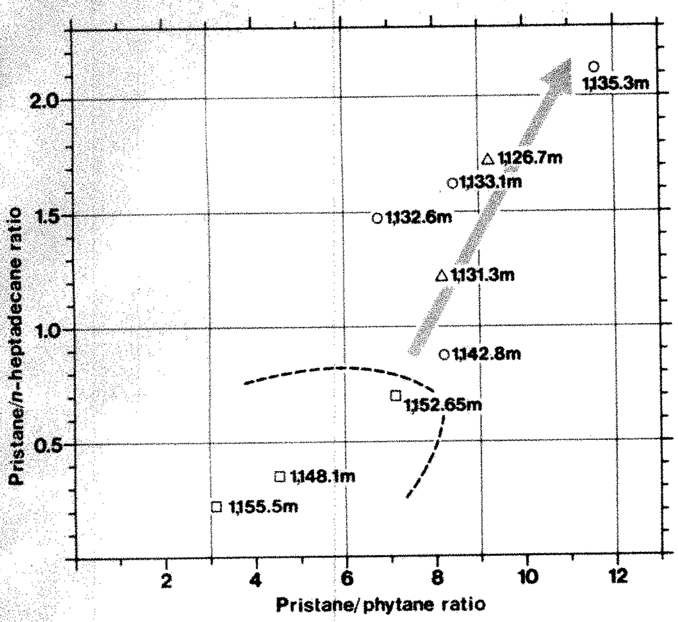

Fig. 3 Pristane/*n*-heptadecane plotted against pristane/phytane concentration ratios for all samples (identified by depth) from the type III kerogen-bearing source rock unit shown in Fig. 1. Note that the original composition largely preserved in the centre of this shale unit (squares) is altered more and more with increasing degree of hydrocarbon expulsion as indicated by the depleted samples (circles, from edge of this shale unit; triangles, thin, highly depleted shale interbeds from overlying sandstone unit). Arrow indicates the shift with increasing degree of expulsion.

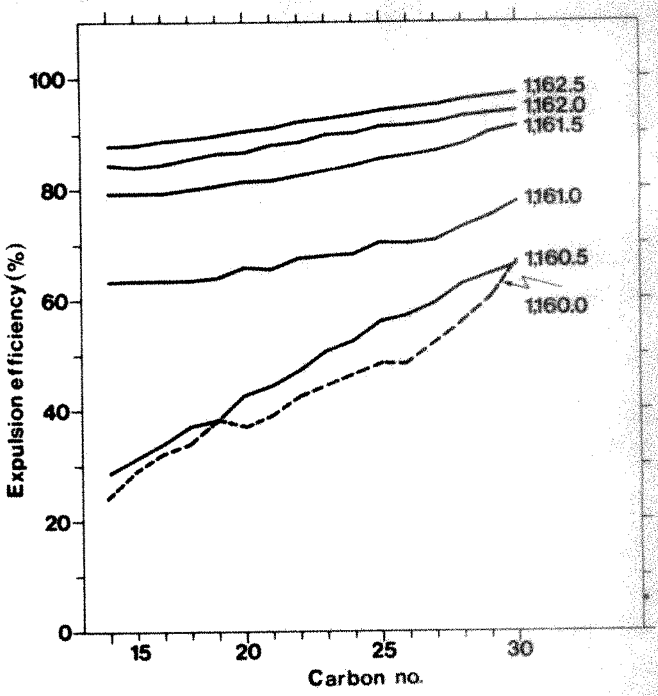

Fig. 4 Efficiencies of expulsion (as % of the unmodified sample 1,159.5 m) of individual *n*-alkanes as a function of carbon number and depth for all samples from the lower depletion interval (defined in Fig. 1), corehole Kökelsumer Heide No. 1, Ruhr district, FRG.

sandstone layers between 1,167.0 and 1,180.0 m are possible avenues because the Katharina coal seam shows a similarly severe depletion of hydrocarbons as previously observed nearby[12]. That the expulsion efficiencies are highest at 1,135.3 m within the upper depletion interval, and not at the shale/sandstone contact itself, suggests that increased depletion into a fracture zone between 1,135.0 and 1,135.2 m has occurred[6].

The conclusions reached from Fig. 1 support the hypothesis that primary migration is associated with chromatography-like fractionation effects according to polarity. Most importantly, however, the observations from Fig. 1 help to solve the controversy over whether primary migration of oil occurs as a separate phase, or dissolved in water. The major difference in maximum expulsion efficiency between the upper and the lower depletion interval (Fig. 1) supports an oil-phase migration mechanism. Based on the relationships between kerogen-types and hydrocarbon generation[1,2,8], it can be deduced that at the time of expulsion the oil saturation of the pore system must have been much higher in the lower source rock interval. More oil was generated there per unit pore volume due to the higher organic carbon content and the superior kerogen quality. In analogy with fluid flow in reservoir sandstones[13], relative permeability and hence expulsion rates for oil from source rock shales are believed to increase drastically if oil saturation of the pore fluid exceeds ~40% (ref. 14). As this value is clearly in excess of the solubility limit for oil in water (even at the maximum temperature and pressure conditions endured by this sequence) oil must have existed in the pore system as a separate phase in this rich source rock unit. While the expulsion efficiency for the total extract (which is indicative of the total oil) reached a maximum of 80% in the rich, lower source rock interval it reached only a maximum of 30% in the less prolific upper source rock interval. Due to the low concentration of organic carbon and the low hydrocarbon generation potential of the kerogen oil, saturation of the pore system must, even at peak generation stage, have remained very small, resulting in low values of the relative permeability and hence low expulsion rates for the oil.

The increasing expulsion of the saturated hydrocarbons in proximity to the upper and lower shale contact is shown by the data in Fig. 2. In comparison with the unmodified samples from 1,148.1 and 1,159.5 m, the samples closer to the outer shale contacts exhibit increasingly lower concentrations (μg per g C_{org}) of normal and isoprenoid alkanes. From the upper depletion interval, pristane is expelled to a lesser degree than its *n*-alkane isomer, as revealed by its gradual emergence over the *n*-alkane distribution envelope with increasing depletion. A corresponding effect cannot be observed in the lower depletion interval, because this source rock has, in accordance with its superior kerogen quality (type II), generated a hydrocarbon mixture with a very low relative proportion of pristane.

The compositional fractionation effects associated with expulsion of the saturated hydrocarbons from the upper depletion interval are shown in more detail in Fig. 3. The three samples analysed from the central portion of this source rock interval (1,148.1, 1,152.65 and 1,155.5 m) have the lowest pristane/*n*-heptadecane and pristane/phytane concentration ratios. With an increasing degree of hydrocarbon expulsion into the overlying carrier bed both compound ratios attain higher values, indicating a general depletion trend as shown in Fig. 3. Pristane is expelled less effectively than *n*-heptadecane and phytane, even less so. Furthermore, the ratios for the two thin source rock-type shales (at 1,131.3 and 1,126.7 m) interbedded in the overlying reservoir sandstone unit, and the sample 1,135.3 m near the fracture zone, imply the expected high degrees of hydrocarbon expulsion (Fig. 3). Both parameters have traditionally been used in petroleum geochemistry in a different way: the pristane/*n*-heptadecane ratio to monitor maturity progress[15] and the pristane/phytane ratio to indicate the organic facies[16-18]. We have also demonstrated here that regular changes, especially of the pristane/*n*-heptadecane ratio occurring over relatively narrow depth intervals, and independent of changes in kerogen-type, can be used to monitor the degree of hydrocarbon expulsion from the source rocks.

The efficiencies of expulsion of individual *n*-alkanes were quantified for the deeper interval utilizing the concept explained above (Fig. 4). For any given *n*-alkane in the molecular range C_{15}-C_{30}, the expulsion efficiency increases drastically from the slightly depleted samples at 1,160.0 m and 1,160.5 m, to the moderately depleted one at 1,161.0 m to the highly depleted samples between 1,161.5 and 1,162.6 m close to the lower contact of this shale unit. Among the latter samples the expulsion efficiencies of the *n*-alkanes vary between ~80 and 95%. The higher molecular weight *n*-alkanes have apparently been expelled to a greater extent. However, the trends shown in Fig. 4 are the result of several processes occurring in the sequence: initial hydrocarbon generation-expulsion-replenishment by subsequent hydrocarbon generation. Therefore, these trends could be explained if, after the main phase of expulsion, hydrocarbon generation continued and, due to the high maturity level of this source rock, mainly lower molecular weight alkanes were formed and added to the unexpelled remainder: erroneously low expulsion efficiencies are apparent from Fig. 4 for the lower molecular weight *n*-alkanes. This effect is observed best near the inner edge of the depletion interval (samples at 1,160.0 and 1,160.5 m); due to the more efficient expulsion of the alkanes generated later, the effect is increasingly obliterated towards the outer shale edge.

The values determined in this study for the expulsion efficiencies should not be considered as absolute. The values depend on whether the sample chosen contains the *in situ* generated hydrocarbon concentrations. It is possible that even the samples from the centre of both source rock units have expelled some of their generated oil. Nonetheless, our conclusions remain valid: the values of the expulsion efficiencies are minimum values and the relative differences in the degree of depletion within the shale edges remain the same.

The results of this study have implications for applied petroleum geochemistry. We have shown that, within an individual source rock body, expulsion efficiencies are variable: they change as a function of proximity to the carrier beds and migration avenues and vary with compound-type, molecular size and structure. It may, therefore, be difficult to select approximate mean values for the expulsion efficiencies of entire source rock units so as to calculate the amount of oil which migrated and possibly accumulated in the traps of a given exploration area. Previously reported values for the efficiency of petroleum expulsion from shale source rocks were much lower (10–15%)[1,2] than the ones documented in this study. However, as previous researchers used a completely different approach (hydrocarbon budget estimates for entire shale and reservoir rock volumes of whole basins), the expulsion efficiency values reported here may not contradict previous experiences. Further work utilizing the approach discussed above should document the natural range of variation of the thicknesses of the depleted edges of average source rock shales at different maturity stages. Another implication of the conclusions reached in this study concerns source rock/crude oil correlation: to establish genetic origins of crude oils more convincingly, an understanding of the nature of hydrocarbon expulsion processes and the associated compositional fractionation effects is required.

We thank the Ruhrkohle AG, Essen, for supplying the sample material, Dr A. S. Mackenzie (BP Research Centre) for a careful review and Dr D. H. Welte (KFA) for support and advice.

Investigation of claims for interstellar organisms and complex organic molecules

Robert E. Davies*†, **Adelaide M. Delluva*** **& Robert H. Koch**†

*Laboratories of Biochemistry, Department of Animal Biology, School of Veterinary Medicine, and † Department of Astronomy and Astrophysics, University of Pennsylvania, Philadelphia, Pennsylvania 19104, USA

For many years, Hoyle, Wickramasinghe and their associates have examined interstellar (IS) absorption features in the ultraviolet, visible and infrared and 'identified' them with a variety of organic structures or organisms. Among these there have been generalized, pre-biotic molecules[1], polyoxymethylene whiskers[2], polysaccharides and hydrocarbons[3,4], tryptophan (and inferentially proteins)[5]—all claimed to be coatings on IS grains. In other cases, the grains[1,6] have been described as 10–100% alkanes, alkenes, alkynes or aromatics by mass. In extensions of these claims, the grains are supposed to be microorganisms (such as viruses and bacteria[7], algae[8], siliceous cells similar to diatoms[9], yeasts[10] or other eukaryotic cells[11]) in whole or in part. Finally, a case has been advanced for possible interstellar and interplanetary insects[11]. The 'identifications' in these and many other publications call into question the intrinsic origin of Earth life itself[12,13] and the uniqueness and validity of darwinian evolution[11]. We now report on ultraviolet spectra of specimens of the types cited by these workers and compare our results with infrared and ultraviolet data published previously. We conclude that the identifications claimed by Hoyle, Wickramasinghe and their colleagues are unwarranted.

The UV results are based on spectrophotometry with the OAO 2 and IUE spacecrafts. Accuracies for these measurements fall in the range ±5 to ±20% depending on the specific wavelength and star and on the observing circumstances. Speakers at a special meeting of the Royal Astronomical Society[14] noted that IUE spectra may be degraded over extended wavelength intervals (specifically near 280 nm)[5] and by saturation losses from over-exposure. The visible-band observations concern weak and diffuse absorption bands in the blue through the red and the accuracies of the measurements made on these bands are commonly of the order of ±10%. For the IR data beyond 2 μm, accuracy is improving very rapidly and, whether from ground (with its restricted wavelength coverage) or from an airborne observatory, is about ±5%. For all these data, spectral resolution (Δλ/λ) is of little consequence as the claims of Hoyle, Wickramasinghe and their colleagues all concern relatively broad

Table 1 Comparison of the Karim *et al.* absorption feature with present measurements of tryptophan near 280 nm

Wavelength (nm)	ΔA*	A†
310	0.00	0.00
300	+0.24	+0.04
290	+0.50	+0.52
280	+0.61	+0.61
270	+0.58	+0.55
260	+0.47	+0.37
250	+0.20	+0.18
240	0.00	+0.12
230	−0.02	+0.91

† Wavelength in nm of measured peak absorption.

‡ Where λ′>200 nm, the sample has an absorbance, >2.000, which cannot be recorded accurately at wavelengths ⩾200 nm.

bands. We have already commented[15] on the treatment of the astronomical data set which Karim *et al.* claimed "confirms" the presence of proteinaceous material in grains[5]. In their Figs 3-5, Karim *et al.* noted the similarity of the absorption spectrum of tryptophan from 310 to 240 nm (including its peak at 280 nm) to a band, nominally freed of the contribution from IS graphite, derived from the ratios of UV spectra of distant, reddened stars to those of nearby comparison stars. Our comments referred to serious mismatches between the paired program and comparison stars and to the reasons why their detailed calculations of the residuum from a particular graphite absorption cannot be defended. However, this property of tryptophan cannot be used alone for identification; this is clear from a perusal of the 118-volume *Sadtler Standard Spectra Collection* which records the UV spectra from 300 to 200 nm of over 34,000 organic compounds. Hundreds of these spectra show peak absorptions with central wavelengths and bandwidths comparable with those of the feature singled out by Karim *et al.*[5]. Furthermore, they represent only a fraction of the several millions of organic compounds now known. Consequently, any particular peak is not specific for any particular molecule, and thus UV spectra alone cannot be used for identification although they may be used to exclude an identification with certainty.

We have, therefore, measured the UV absorbances (which in some cases include the effects of scattering) of some molecules and primitive life forms, including several types which Hoyle and Wickramasinghe have suggested or claimed to exist in IS space.

Absorption spectra were measured accurately from 320 to 235 nm or less in quartz cuvettes (1 cm light path) by means of a Bausch and Lomb Houston Instrument Omniscribe D-5000 strip chart recorder attached to a Varian DMS 90 UV-Visible Spectrophotometer. In all cases except tryptophan, whenever the lowest recorded value was above 200 nm this was because the absorbance had gone off scale (>2.0) and remained there at all wavelengths down to 200 nm. The region below 240 nm is where the excess absorbance of the Karim *et al.* feature has an absorbance of 0.02 or less. The absorption spectra were obtained for the amino acid tryptophan, the protein bovine serum albumin (BSA), the nucleic acids calf thymus DNA and *Micrococcus luteus* DNA, the bacteriophages M13 and ΦX174, the nuclear polyhedrosis virus (NPV) that attacks the wax moth *Galleria mellonella*, the Gram-positive bacterium *Bacillus cereus*, the Gram-negative bacterium *Escherichia coli* JM 103, the cyanobacterium (blue-green alga) *Merismopedia*, the diatom *Aehnanthes brevipis*, and the green alga *Chlorella*. The spectra for tryptophan, BSA, the DNAs, NPV, *E. coli* and *B. cereus* were also measured on thin films of the dry materials because there would be no free liquid water on interstellar grains.

Table 1 compares our experimental results for tryptophan with the excess extinction from Figs 3 and 5 of Karim *et al.* Disagreement between the two spectra is conspicuous at wavelengths below 240 nm. Our complete results appear in Table 2. For all specimens with an absorption peak in the region 290-250 nm that was different from that at 280 nm, the absorption ratios are even larger when calculated for a standard wavelength of 280 nm.

The results show that, whereas tryptophan and BSA in solution had peaks near 280 nm, every other sample of our materials had a peak near 260 nm that was clearly dominated by the nucleic acids present[16]; this does not agree with Karim *et al.*'s expectation[5] that organisms or their dry remains would have a peak of their UV absorption spectra at or near 280 nm. The effect of drying depended on the size and shape of the particles or crystals formed. For tryptophan, for example, differential scattering can change the position of the observed peak by tens of nanometres and also flatten it conspicuously. In general, absorption peaks are affected by the solvent and its *p*H—a phenomenon known as 'the universal redshift'[17].

For each one of the wet or dry specimens the absorption band from 210 to 200 nm was higher than the peak between 290 and 250 nm. This finding alone undermines the basis on which Karim *et al.* claimed[5] to have confirmed the presence of proteinaceous material on IS grains. This claim depended on the almost complete lack of absorption from 240 to 180 nm (see their Fig. 3) by the unknown material they believed responsible for their 280 nm peak. Figure 3 of Karim *et al.*[5] was normalized at both the 310 nm and 220 nm peaks. This 280 nm peak is the only one within the recorded range of wavelength. It follows that substances or organisms with higher absorbances below 240 nm than at 240 nm must be excluded. This property was found in dry tryptophan and in each of the other materials and organisms tested. For tryptophan in solution, a peak at 220 nm was followed by a shallow trough at 210 nm, then by higher absorbances at and below 200 nm—this particular detail also excludes the identification.

Setlow and Doyle[18] recorded the absorption spectra of dry samples of the protein trypsin and of aldolase and RNase from 310 to 185 nm. All these proteins had absorption peaks at 280 nm but absorbed (and scattered) the incident radiation much more effectively at and below 240 nm. The ratios of the molar absorption coefficients were 32, 50 and 63 for $\varepsilon_{200}/\varepsilon_{280}$ and 8.6, 12.5 and 13.6 for $\varepsilon_{220}/\varepsilon_{280}$. These ratios are so large that, if proteins were the source of the absorption, the contribution from graphite would be negligibly small and the curve for HD14250 and its comparison star in Fig. 3 of Karim *et al.* would not have the observed shape.

Although the higher absorption of tryptophan in solution at 230 nm (compared with that at 280m) was shown in Fig. 1 of Karim *et al.*[5], it was neglected in their Fig. 5 which compared "the excess extinction in the star HD14250 relative to graphite" (spheres of 0.02 μm radius). This comparison was given only from 310 to 245 nm where the curves fit but not for points below 240 nm and especially below 220 nm where the discrepancy becomes increasingly large. A similar objection follows from the papers[19,20] which Karim *et al.* cite concerning the proteins of tobacco mosaic virus and the envelope proteins of *E. coli*; these papers show a higher absorption for these proteins at or below 240 nm than at 280 nm. This peak is also claimed to confirm the proteinaceous material in grains[5] from dried bacteria and algae[8] and viruses[13].

Karim *et al.* state that "DNA has a strong absorption at 2,600 Å . . . but the DNA content of microorganisms is so small that prospects of detecting this particular absorption are not encouraging". However, the content of the various ribonucleic acids is very high[21] and the spectra of the corresponding ribo- and deoxyribonucleotides as well as nucleosides are essentially identical[16]. The molar absorption coefficients of the various nucleotides at 260 nm are greater[16] (≈9,000 to ≈15,000) than that of tryptophan ($\approx$5,000) at 280 nm. Furthermore, tryptophan comprises only 3 of the 336 amino acids in each *E. coli* envelope protein, but 25 of the amino acids are tyrosine and this moves the peak absorption to 275 nm (ref. 20). This accounts for *E. coli* and the other organisms enumerated above having peaks near 260 nm rather than 280 nm.

It is well known that the sterilization action spectrum of UV radiation from 300 to 220 nm parallels the absorption spectrum of bacteria[22,23] and that enzymes are inactivated by UV-induced damage to phenylalanine, tyrosine, tryptophan and cystine[24]. If tryptophan and these other amino acids were exposed to the interstellar UV, they would soon be destroyed. For example, the quantum yield for the production of ammonia, by 253.7-nm radiation, from tryptophan is 0.002 (ref. 24). If the amino acids were protected deep inside a grain covered by a polymeric coat, they could not be observed. However, a literature search failed to uncover any finding of tryptophan or any other indole derivative in either meteorites or IS clouds. One paper[10] concludes that the IR spectrum of the galactic centre source IRS7 contains strong evidence for bacterial grains on the basis of the IR spectrum of *E. coli*. However, from these results we have calculated that the same bacterial mass would cause an absorbance $\approx$100 times larger in the UV than in the IR and this has not been observed in the direction to any star. The same comparison excludes polysaccharides[25,26] associated with diatoms[9] and algae[8]. Finally, on the basis of experiments of Rosenbusch[20] and Setlow and Doyle[18], pure proteins in general[5,10] (including the major envelope protein of *E. coli*[20]) have a maximum UV absorbance at least 100 times larger than the highest IR absorbance. Because neither the required shape nor magnitude of the UV absorbances are observed, proteins are also excluded as explanation for these absorbances.

After this work was completed, Williams[27] and Hoyle and Wickramasinghe[28] published letters also describing the recent adverse comment[14] on the conclusions of Hoyle, Wickramasinghe and colleagues. Turner[29] expressed the need for much more stringent requirements than have recently been applied for molecular identification in the microwave region; although he is concerned only with highly resolved spectra, the same constraints apply even more forcibly to presently resolvable IR and UV molecular bands.

The M13 and *E. coli* JM 103 were gifts from Dr Roselyn Eisenberg; the DNA samples from Dr Phoebe S. Leboy; the other viruses and living organisms came from the Carolina Biological Supply Co., North Carolina.

Note added in proof: Greenberg's claim (see ref. 14) that the 280 nm feature[5] is spurious has now been published[30] together with summaries of papers given at the Royal Astronomical Society's Specialist Discussion, 'Are Interstellar Grains Bacteria?'[31]. Other adverse comments have appeared[32-35]. The response to these by Karim, Hoyle and Wickramasinghe[36,37] has in turn been answered by us[35].

Major histocompatibility complex (MHC) class I molecules can function as specific target antigens in T-cell-mediated cytotoxity[1,2]. In addition, T cells can kill target cells through non-MHC antigens, for example, virally infected cells, if the target and effector cells express the same MHC class I antigens[2]. Consequently, quantitative and/or qualitative variations in the expression of the H–2/HLA antigens on the target cells could interfere with MHC-restricted immune reactions. We have reported that the AKR leukaemia cell line K36.16, a subline of K36 (ref. 3), on which the H–2K^k antigen cannot be detected, is resistant to T-cell lysis and grows very easily in AKR mice[4]. Other AKR tumour cell lines, like 369, which have a relatively large amount of H–2K^k on their surface, are easily killed by T cells *in vitro* and require a much larger inoculum to grow *in vivo*[4]. Monoclonal antibodies against H–2K^k, but not against H–2D^k, prevented the killing by T cells[4,5]. This suggests that some tumour cells grow *in vivo* because tumour-associated antigen(s) cannot be recognized efficiently by the host's immune system, due to the absence of MHC molecules which would function as restriction elements for T-cell cytotoxicity. We have tested this hypothesis by introducing the *H-2K^k* gene into the H–2K^k-deficient AKR tumour cell line K36.16 and have now demonstrated directly the biological relevance of H–2K^k antigen expression in the regulation of the *in vivo* growth of this tumour cell line.

Transformations were done by calcium phosphate co-precipitation[20] with a cosmid containing the *H-2K^k* gene (c27.2) and pTCF[6], the vector for the aminoglycosyl 3′-phosphotransferase gene (*agpt*), or pTCF alone. Between 8 and 20 transformants per 10^6 cells were selected in medium containing 800 μg ml^{-1} of the antibiotic G418. From over 300 transformants, we selected a series of clones that expressed different amounts of H–2K^k on the cell surface (see below). DNA and RNA were isolated from each of the selected transformants and analysed by Southern blot or S_1 nuclease protection analysis. Hybridization with a plasmid (vector) or an *H-2K^k* probe showed that each of the transformants contained one to three copies of the exogenous *H-2K^k* gene (data not shown). Figure 1 shows the level of *H-2K^k* mRNA determined by S_1 nuclease protection assay in the K36.16 tumour cells before and after transformation with *H-2K^k*. The negative control *H-2K^d* P_3-X63-Ag8 (Ag8) cells[7] (Fig. 1*b*) and the K36.16 cells show a low mRNA signal, probably due to incomplete S_1 digestion of RNA–DNA hybrids

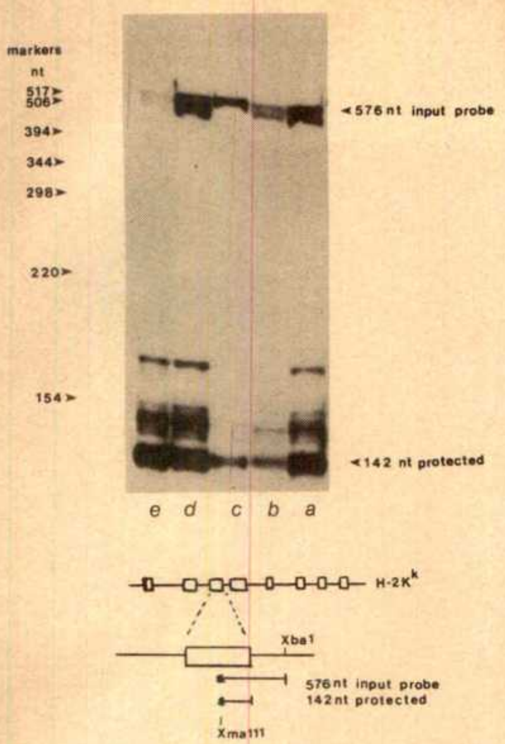

Fig. 1 S_1 nuclease protection analyses of mRNA isolated from the c27.2 transformants and control cell lines: *a*, 369 (H-2K^k, positive control); *b*, Ag8 (H-2K^d, and H-2K^k-negative control); *c*, K36.16; *d*, C27.2.2; and *e*, C27.2.3.

Methods: S_1 nuclease protection analysis was done using procedures described elsewhere[18,19]. The input probe is a 576-nucleotides (nt) *Xma*III-*Xba*I DNA fragment isolated from the third exon-intron boundary; 142 nt of this fragment are protected from S_1 nuclease digestion (S. Kvist, personal communication). 25 μg of total cytoplasmic RNA isolated from the different cell lines were hybridized overnight at 57 °C with the labelled DNA input probe. S_1 nuclease cleavage was at 37 °C for 2 h and electrophoretic separation was on 8 M urea-7% polyacrylamide gels, resulting in a 142-nucleotide protected fragment. Multiple protected bands shorter than 142 nt are due to overdigestion by S_1 nuclease.

formed between the DNA probe and mRNA molecules other than *H-2K^k*. The *H-2K^k*-transformed cells, however, show an increase of at least 20-fold of *H-2K^k* mRNA (Fig. 1*d*, *e*) to a level similar to that of the positive control, 369 (H-2K^k-positive) (Fig. 1*a*). This suggests that the absence of the H-2K^k antigen on the K36.16 cells is due to a failure to transcribe the *H-2K^k* gene efficiently, rather than any post-transcriptional event.

To demonstrate the presence of the H-2K^k antigen on the cell surface, we carried out radiobinding analysis with anti-H-2K^k monoclonal antibodies. Table 1 gives the results from only five *H-2K^k* DNA transformants and the control cell lines, because they cover a wide range of H-2K^k antigen expression on the cell surface and were subsequently used in experiments designed to evaluate the role of H-2K molecules in oncogenesis and host resistance to AKR leukaemias. All these cell lines express the same amount of H-2D^k, as expected (data not shown). In addition, a 45,000-molecular weight molecule was precipitated by anti-H-2K^k monoclonal antibody from ^{35}S-methionine-labelled lysates of one of the transformed clones. Competition by added unlabelled AKR (H-2K^k-positive) lysates specifially prevented the immunoprecipitation of this molecule (data not shown).

Because the H-2K^k antigen is important as a restriction element in T-cell-mediated killing of Gross virus tumours[4], we examined the ability of these transformed clones to induce tumours in syngeneic AKR and semi-syngeneic (AKR × BALB/c)F1 mice. Table 1 shows that inocula of 10^5 viable cells

Table 1 Radioimmunoassay and tumour inducibility of *H-2K^k*-transfected K36.16 cells

Transformant	Radiobinding (net c.p.m.)		No. of mice with tumours*	
K36.16	0	(0)	10/10	(10/10)
pTCF-K36.16	92	(21)	10/10	(10/10)
C27.2.1	364	(424)	0/10	(0/10)
C27.2.2	376	(529)	1/5	
C27.2.3	1,334	(1,073)	0/5	(0/5)
C27.2.4	257	(209)	4/5	
C27.2.5	230	(497)	0/5	
369	19,416	(6,350)		

For radiobinding, 5×10^5 cells were reacted with monoclonal antibodies as indicated. The anti-H-2K^k (refs. 15, 16) and anti-H-2D^k (ref. 15)-producing hybridoma cell lines were obtained from the American Type Culture Collection. The results are an average of two independent assays with anti-H-2K^k antibody 11.4.1 (ref. 15) (or 16-3-22S[16]) and are expressed as c.p.m. after subtraction of the background (200 c.p.m.) pTCF-K36.16 is a clone obtained by transformation of K36.16 with the vector pTCF alone. The positive control, 369, is an AKR leukaemia that expresses H-2 K^k antigen[4].

* 100,000 K36.16 tumour cells (in 0.1 ml phosphate-buffered saline, PBS) were injected subcutaneously (s.c.) into one thigh and the same number of c27.2 transfected clones into the other thigh of the recipient mouse. The diameters of the tumour masses were measured after 3 weeks. Mice were scored as positive for tumours when the diameters measured were 1.5–2.0 cm, whereas mice were scored as negative for tumours when the diameters observed were <0.6 cm. 3,000 K36.16 tumour cells were able to induce 100% tumour incidence in both AKR and (AKR × BALB/c)F1 mice in 14–20 days. The values for F_1 mice are given in parentheses.

Table 2 Induction of tumour by treatment of the transfected clones with monoclonal anti-H-2K^k antibody

Clone	Treatment of AKR recipients	No. of mice with tumours
C27.2.1	Anti-H-2K^k MoAb	3/5
C27 2 1	Anti-H-2K^b MoAb	0/5
C27.2.1	Culture medium	0/5
C27.2.3	Anti-H-2K^k MoAb	6/7
C27.2.3	Anti-H-2K^b MoAb	0/7

100,000 transfected clones treated with monoclonal antibody (MoAb) (anti-H-2K^k MoAb 16-3-22S[16] or anti-H-2K^b MoAb B8-24-3 (ref. 17) as indicated were injected s.c. into the thigh of one of the hind legs of the recipient, and K36.16 cells treated with the same antibody were injected into the other hind leg of the same mouse. This was followed by subsequent injections of the corresponding monoclonal antibody *in vivo* once every other day. The number of tumour incidences was recorded after 20 days. The K36.16 tumour cells were able to induce tumours in all cases.

Table 3 Mice immunized with the transfected clones reject a second challenge of the original K36.16 tumour cells

Mouse strain tested	Mice primed with clone	No. of mice with tumours
AKR	C27.2.3	0/5
AKR	C27.2.3 (mitomycin C)	4/5
(AKR × BALB/c)F1	C27.2.3	0/5
AKR	C27.2.2	0/5
AKR	C27.2.4	0/2
AKR	K36.16 (mitomycin C)	5/5

Mice were injected s.c. with 100,000 c27.2 transfected cells as indicated in Table 1. After 3–4 weeks, mice that did not show signs of tumours were given an additional dose (s.c.) of 100,000 K36.16 tumour cells. The number of mice with tumours was observed after 30 days. The K36.16 (mitomycin C) cells were treated with mitomycin C at 50 μg ml^{-1} 10^6 cells for 30 min at 37 °C, washed four times with PBS and subsequently injected s.c.

of the original K36.16 tumour cells and a clone of K36.16 tumour cells transformed with the vector pTCF alone, induced necrotic tumours within 20 days. However, inocula of 10^5 viable cells each of clones C27.2.1, C27.2.3 and C27.2.5 all failed to induce tumours in AKR and (AKR × BALB/c)F1 mice; these clones were able to induce tumours in all cases when the recipient AKR mice were irradiated (700 rad) before injection. Clones C27.2.2 and C27.2.4, which express relatively lower amounts of H-2K^k antigens (Table 1), were both able to induce tumours in some of the AKR mice. Interestingly, the diameters of the tumour masses which developed after inoculation of the latter clones were smaller (0.9–1.2 cm) and necrosis was absent even after 30 days. The oncogenicity of these transformed clones may thus be determined by: (1) the level of expression of the H-2K^k gene product in a particular transformant; (2) the ability of individual recipient mice to mount an efficient immune response against these inocula; and (3) the size of the inoculum needed to induce a tumour. When a higher dose of 5×10^6 viable cells was given, C27.1.1 and C27.2.3 were able to develop tumours in AKR mice (C27.2.5 was not tested). Conversely, clones C27.2.2 and C27.2.4 failed to induce tumours in AKR mice if a lower dose of 5×10^3 cells, instead of 10^5 cells, was given.

To prove that H-2K^k is the restriction element needed for the *in vivo* rejection of the transformed clones, C27.2.1 and C27.2.3 were first allowed to react separately with several different monoclonal antibodies (as shown by Table 2) before injection into the mice. The corresponding monoclonal antibodies were subsequently injected once every other day for 5 days. This procedure enabled the transformed clones to induce tumours in most AKR recipients (three out of five for C27.2.1, and six out of seven for C27.2.3; Table 2). Injection of the irrelevant anti-H-2K^b monoclonal antibody and culture medium were both ineffective.

To test whether the *H-2K*^{k} DNA-transformed clones can confer immunity, mice were injected with either the transformed clones, or mitomycin C-treated K36.16 tumour cells or C27.2.3 cells as indicated in Table 3. After 3 weeks, mice that did not show signs of tumours were again challenged with an additional 10^5 live K36.16 tumour cells. While only 3×10^3 K36.16 tumour cells always produced a tumour, the mice which had rejected the *H-2K*^{k}-transformed K36.16 clones were protected against a subsequent challenge of 10^5 live K36.16 tumour cells—this even included mice which had rejected the relatively low H-2K^k-expressing clone C27.2.4. Thus, once an efficient immune response was obtained, this protective immunity was as efficient as that elicited by the more immunogenic clones (for example, C27.2.3) against a subsequent challenge of the original K36.16 tumour cells. When the H-2K^k-positive C27.2.3 cells were prevented from dividing by treatment with mitomycin C before injection, their ability to induce protection against a second challenge of live K36.16 tumour cells was abrogated (Table 3).

These experiments raise several interesting questions. First, the importance of the expression of the H-2K^k product seems to be central to the host reponse to tumours. The examination of many AKR tumours showed that several of them had only a small amount of H-2K^k antigen on the surface[4]. These findings and those of others[8-11] suggest that the relative absence of the H-2K specificity provides such tumours with a selection advantage *in vivo*[12,13]. One might expect, as indeed is found, that the cell-mediated cytotoxicity of tumours which are H-2D-restricted would exhibit a relative absence of the *H-2D*-encoded products[14].

The results presented here strongly suggest that the selective loss of the H-2K^k restriction elements in K36.16 is caused by a 'switch-off' at the transcriptional level, rather than any changes in the amino acid sequences or any fault in the mechanism necessary for the insertion of the antigens in the cell membrane. Experiments to study the molecular basis of this suppression are in progress.

We thank M. Steinmetz for the cosmid c27.2; S. Kvist for providing unpublished information in preparing the *H-2K*^{k} DNA probe for the S_1 nuclease protection analysis; and C. O'Carroll for typing the manuscript. The '369' tumour line was provided by Peter Krammer. These studies were supported by the CRC and the MRC (UK).

Insertion of *N* regions into heavy-chain genes is correlated with expression of terminal deoxytransferase in B cells

The variable regions of immunoglobulin heavy chains are encoded in the germ line by three discrete DNA segments: V_{H} (variable) elements, *D* (diversity) elements and J_{H} (joining) elements. During the differentiation of B lymphocytes, individual segments from each group are brought together by recombination to form the complete $V_{\mathrm{H}}DJ_{\mathrm{H}}$ variable region[1-8]. To understand these processes better, we have now isolated and sequenced molecular clones representing intermediates (DJ_{H} fusions) and final products (V_{H}-to-DJ_{H} joins) of heavy-chain gene rearrangement in two cell lines[9,10] that represent analogues of cells at early stages of B-lymphocyte differentiation[11-13]. Heavy-chain gene assembly in one cell line but not in the other is accompanied by the appearance of short nucleotide insertions at the recombinational junctions. The generation of such insertions is positively correlated with the expression of terminal deoxynucleotidyl transferase in these lines.

The two cell lines used in our study, 40E4 and 22D6, were produced by Abelson murine leukaemia virus (A-MuLV) transformation of BALB/c fetal liver at 13–14 and 17–19 days of gestation, respectively. These cell lines produce no detectable immunoglobulin[12]; they possess DJ_{H} rearrangements on both chromosomes and undergo further rearrangement during propagation[12-14]. Thus the 40E4 and 22D6 cell lines seem to represent the stage of differentiation during which lymphoid progenitor cells give rise to μ-positive pre-B cells.

Two clonal cell lines, 40E4-2 and 22D6-G, were isolated, carried in culture for about 25 generations and subcloned to generate sets of secondary clonal isolates. The clonal origin of these isolates was verified by analysis of the pattern of A-MuLV

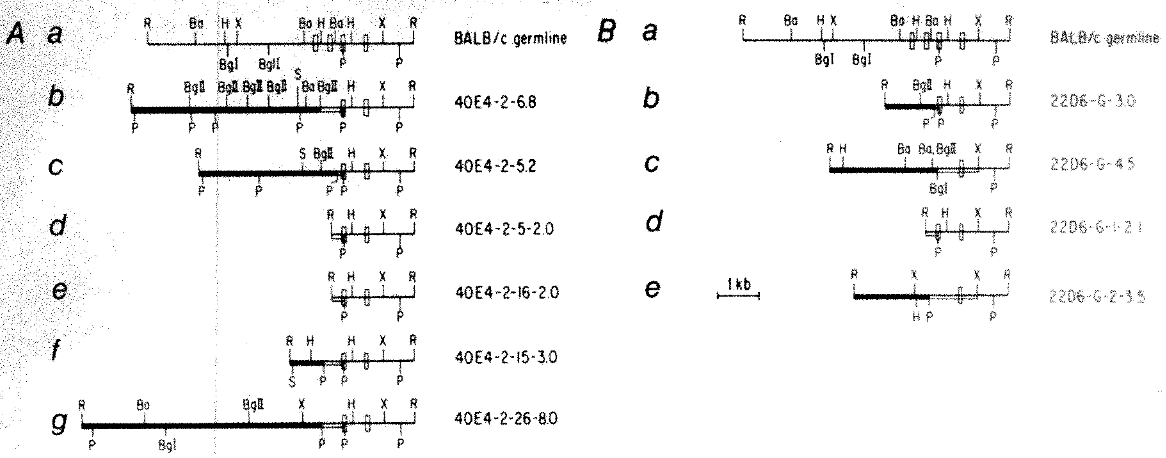

Fig. 1 Restriction maps of molecular clones representing J_H-associated rearrangements in derivatives of 40E4-2 and 22D6-G. *A*, Partial restriction maps of recombinants from 40E4-2 and its derivatives. *a*, Map of the 6.2-kb J_H-containing *Eco*RI fragment from the BALB/c germ line[3], shown for comparison. *b–f*, Restriction maps of the following J_H-associated rearrangements: *b*, 40E4-2-6.8; *c*, 40E4-2-5.2; *d*, 40E4-2-5-2.0; *e*, 40E4-2-16-2.0; *f*, 40E4-2-15-3.0; *g*, 40E4-2-26-8.0. Narrow lines represent regions of identity with the BALB/c germ-line map. Closed bars represent the minimal extent of novel DNA sequence; open bars designate the localization of the recombinant junctions. Restriction enzymes are abbreviated as follows: R, *Eco*RI; Ba, *Bam*HI; H, *Hin*dIII; X, *Xba*I; P, *Pst*I; Bgl, *Bgl*I; BglI, *Bgl*II; S, *Sac*I. *B*, Partial restriction maps of recombinants from 22D6-G and its derivatives: *a*, the BALB/c 6.2-kb germ-line *Eco*RI fragment; *b*, 22D6-G-3.0; *c*, 22D6-G-4.5; *d*, 22D6-G-1-2.1; *e*, 22D6-G-2-3.5. Regions of novel DNA sequence and locations of recombinant junctions are identified as in *A*.

Methods: Genomic DNA libraries for each of the A-MuLV-transformed parental cell lines and their derivatives were constructed in Charon 16A and screened for hybridization to a J_H probe[14]. J_H-containing bacteriophage insert fragments were subcloned into the *Eco*RI site of pBR322 and partial restriction maps were determined. The A-MuLV-transformed cell lines were produced as described by Rosenberg and Baltimore[9] and Waneck and Rosenberg[10]. Cell lines were cultured in RPMI-1640 medium supplemented with 10% heat-inactivated fetal calf-serum and 50 μM 2-mercaptoethanol. Primary subclones 40E4-2 and 22D6-G were derived from the 40E4 and 22D6 cell lines by limiting dilution to a concentration of 0.2 cells per microtitre well. These primary subclones were carried for 2 weeks in culture and secondary subclones were obtained by limiting dilution as described above. Preparation of genomic DNA, restriction enzyme digestion, agarose gel electrophoresis, radiolabelling of probes by nick-translation and DNA hybridization were performed as previously described[29]. Genomic DNA libraries were constructed in the bacteriophage vector Charon 16A[30]. Genomic DNA from 40E4-2, 40E4-2-26, 22D6-G or 22D6-G-2 was digested with *Eco*RI and ligated to Charon 16A DNA, which had previously been digested with *Eco*RI and dephosphorylated with calf intestinal phosphatase. Genomic DNA from 40E4-2-5, 40E-2-15, 40E4-2-16 or 22D6-G-1 was cut with *Eco*RI and fractionated on gradients of 10–40% sucrose containing 1 M NaCl, 20 mM Tris-Cl *p*H 8.0 and 10 mM EDTA. Centrifugation was performed at 24,000 r.p.m. and 20 °C for 24 h in the SW27 rotor. Fragments <2.5 kb long were selected from digests of 40E4-2-5, 40E4-2-16 and 22D6-G-1 genomic DNA; fragments <3.5 kb long were selected from the digest of 40E4-2-15 genomic DNA. These size-selected pools were ligated to Charon 16A DNA, prepared as described above. The products of ligation were encapsidated *in vitro* by the method of Sternberg *et al.*[31]. The resultant bacteriophage were propagated in *Escherichia coli* strain LE392. Plaques were screened for hybridization to the ^{32}P-labelled J_H probe by the method of Benton and Davis[32]. Bacteriophage positive for hybridization were isolated by three additional rounds of plaque purification. After initial propagation in Charon 16A, the J_H-containing *Eco*RI fragments were subcloned into the *Eco*RI site of pBR322.

proviral integration[15], which was identical among all members of each set of subclones (data not shown). Hybridization of J_H and D probes to DNA from both series of clonal cell lines showed that each parental line had two DJ_H rearrangements and that many subclones had lost one or both DJ_H-containing fragments but had acquired new fragments[14]. The new fragments generally hybridized well to the J_H probe but not to the D probe, suggesting that they might have arisen by appendage of V_H segments onto pre-existing DJ_H units.

To determine the structures of the J_H-associated rearrangements present in the 40E4-2 and 22D6-G cell lines and their derivatives, we carried out molecular cloning of each putative V_H-to-DJ_H rearrangement. The restriction maps of the fragments and their relationship to the J_H region of BALB/c germ-line DNA are shown in Fig. 1. In the 40E4-2 series, the original DJ_H rearrangements were near J_H3 and further rearrangements also occurred near J_H3. In 22D6-G, one rearrangement was near J_H4 and the other near J_H3; the subclones had secondary rearrangements near the same regions. The areas around these points of rearrangement were therefore chosen for DNA sequence analysis.

From its sequence, it is evident that the 5.2-kilobase (kb) J_H-containing *Eco*RI fragment from the 40E4-2 line had arisen by recombination between an SP2-type D segment[8] and J_H3 (Fig. 2*A*, *a–c*). The 5′ flank of the D region and part of its coding sequence are totally homologous to $D_{SP2.7}$ but, as is often found at DJ_H joints[2,5–8], some nucleotides were apparently lost from both the D and J_H potential coding sequences. Also, 7 nucleotides not represented in the $D_{SP2.7}$ or J_H3 germ-line sequences were found between D and J_H; they constitute an N region[16]. A similar analysis of the sequence in the 6.8-kb allele showed that it, too, consisted of part of D, part of J_H3 and an N region of 4 nucleotides (Fig. 2*B*). The exact germ-line sequence for this allele is not known, although it is most similar to $D_{SP2.3}$ (see Fig. 2*B*).

The alleles cloned from 22D6-G had also lost some coding sequence from J_H or D (Fig. 3*A*, *a–c*; *B*, *a–c*). Both D regions were identical to known germ-line D segments. The rearrangements differed from rearrangements in 40E4-2 in that all of the nucleotides near the joints could be accounted for by D and J_H germ-line sequences; no insertion of N regions seemed to have occurred.

The presence of the highly conserved[17] 3′ end of the V_H segment in all four secondary rearrangements of the 5.2-kb DJ_H-containing *Eco*RI fragment in 40E4-2 and both rearrangements in 22D6-G shows that all of these rearrangements involved recombination of V_H segments with pre-existing DJ_H segments (Figs 2*A*, *e–h*; 3*Ae*, *Bd*). All six of these V_H-to-DJ_H rearrangements have used closely related members of the V_H7183 gene family, of which the MOPC21 V_H gene is representative[18]. In all but one case, whenever a new band appeared in a subclone, the new fragment contained the DNJ_H structure characteristic of the fragment that had been lost (see Figs 2, 3), proving that a pre-existing DJ_H gives rise to a V_HDJ_H unit.

The junctions formed during V_H-to-DJ_H joining were similar in several respects to the junctions formed during D-to-J_H joining. First, there was loss of a variable number of nucleotides from the 5′ end of the DJ_H coding sequence. Second, variable numbers of nucleotides were lost from the 3′ ends of the V_H coding sequences. This was definitively observed in the

Fig. 2 V_H–DJ_H assembly in the 40E4-2 A-MuLV transformant. ***A***, Primary and secondary rearrangement of the 5.2-kb J_H-containing *Eco*RI fragment from 40E4-2. Recombinant junctions in molecular clones of the primary (5.2 kb) and secondary rearrangements were localized by restriction mapping, and nucleotide sequences across the joints were determined by the method of Maxam and Gilbert[33]. *a*, *b*, Partial sequences of the germ-line J_H3 segment[3,7] and $D_{SP2.7}$ segments[8]. *c*, Sequence of the $D_{SP2.7}$-J_H3 fusion in clone 40E4-2-5.2. *d*, 3′-Terminal portion of the germ-line sequence of the V_H81X gene segment[18]. *e*, *f*, Sequences at the recombinant junctions of clones 40E4-2-5-2.0 and 40E4-2-16-2.0; these recombinants resulted from joining of V_H81X to the D-J_H3 fusion of 40E4-2-5.2. *g*, *h*, Sequences at the recombinant junctions of clones 40E4-2-15-3.0 and 40E4-2-24-8.0; these rearrangements are also the result of V_H-to-DJ_H joining. Sequences derived from J_H coding regions are indicated by a dashed underline; sequences derived from D regions are given in boldface type. Conserved heptamer and nonamer recognition sequences are indicated. Nucleotide regions not accounted for by germ-line V_H, D or J_H sequences (N regions) are enclosed in boxes and labelled N. Dotted boxes designate probable N regions in instances where the precise germ-line sequence of one recombination partner has not been determined (see text). Loss of nucleotides from the 5′ or 3′ side of a coding segment is designated by 'X or X′, respectively. ***B***, Primary rearrangement of the 6.8-kb J_H-containing *Eco*RI fragment from 40E4-2. The recombinant junction in the 6.8-kb fragment was localized by restriction mapping and the nucleotide sequence across the joint was determined as above. *a*, *b*, Partial sequences of the germ-line J_H3 and $D_{SP2.3}$ segments[8]. *c*, Sequence of the D-J_H3 fusion in clone 40E4-2-P-6.8. The D segment used is not identical to any known D segment, although it is similar to $D_{SP2.3}$. The hyphen indicates a gap introduced in the D coding region to maximize homology to $D_{SP2.3}$. Symbols used are defined in *A*.

recombinants 40E4-2-5-2.0 and 40E4-2-16-2.0 both of which used the V_H81X segment[18] and lost one and two nucleotides, respectively, from its 3′ end (Fig. 2*Ad*–*f*). Comparison with related V_H sequences[17] suggests that the V_H segment used in 40E4-2-15-3.0 has probably lost no nucleotides whereas the V_H segment used in 40E4-2-26-8.0 has lost at most one (Fig. 2*Ag*, *h*).

A third characteristic of V_H-to-DJ_H joining was that nucleotides not present in the germ-line sequences appeared at the V_H–DJ_H junction in at least one and probably two of the four secondary recombinants derived from 40E4-2. In 40E4-2-5-2.0, two dG residues appeared at the boundary between V_H81X and D, neither of which was present in the germ-line V_H81X segment or the parental DJ_H segment. Using related V_H segments[17] for comparison, it seems likely that five nucleotides (TAAGG) had been introduced at the V_H–DJ_H junction in 40E4-2-15-3.0 which were not encoded by either V_H or the parental DJ_H segment.

As in the 40E4-2 derivatives, the V_H–DJ_H junctions in the 22D6-G subclones exhibited variable loss of nucleotides from the V_H and DJ_H coding segments. In neither recombinant, however, did we find nucleotides at the V_H–DJ_H junction that could not be accounted for by the DJ_H or V_H sequences.

Comparison of the V_HDJ_H segments found in derivatives of 40E4-2 and 22D6-G revealed one obvious difference: recombinants from the 40E4-2 line commonly contained extra nucleotides not encoded by V_H, D or J_H segments whereas recombinants from the 22D6-G line did not. These N regions, which have also been found in DJ_H and V_HDJ_H fusions from terminally differentiated cell lines[5,6,8,16], vary widely in length and sequence and it therefore seems unlikely that each is encoded in the germ line. It has been suggested that extra nucleotides might be introduced at D–J_H and V_H–DJ_H junctions by the enzyme terminal deoxynucleotide transferase (TdT) during recombination[16]. This enzyme, which is present in several lymphoid lines[19], is capable of catalysing polymerization of deoxyribonucleotides onto the 3′-hydroxyl terminus of an oligonucleotide primer in the absence of a template[20]. In an attempt to correlate the expression of TdT in the 40E4-2 and 22D6-G lines with their ability to introduce extra nucleotides at the junctions of V_H, D and J_H segments, extracts prepared from these cell lines were assayed for TdT activity, as indicated by polymerization of dGTP onto an oligo(dA) primer[21,22]. In the presence of extract from 40E4-2 (16 μg protein), 10.0 pmol dGMP was incorporated into acid-precipitable material in 60 min at 37 °C, a level similar to that of the TdT-containing thymoma line, RL♂11. In contrast, we were unable to detect polymerization in the presence of an extract from 22D6-G cells (<0.2 pmol dGMP incorporated). Addition of extract from 22D6-G did not inhibit polymerization catalysed by the 40E4-2 extract. To confirm these results, the cell lines RL♂11, 40E4-2 and 22D6 (the parental line from which 22D6-G was cloned) were metabolically labelled with ^{35}S-methionine and extracts of these cells were assayed by immunoprecipitation with affinity-purified anti-TdT antibody. A protein of the size of TdT was precipitated from RL♂11 and 40E4-2 but not from 22D6 (Fig. 4). Also, a partial cDNA clone for TdT has been observed to hybridize to a 2.2-kb RNA species present in RL♂11 and 40E4-2 but not in 22D6 (N.L. and D.B., unpublished observations).

For five of the six V_H-to-DJ_H rearrangements that we examined, we were able to identify unambiguously in the parental cell the DJ_H segment that had participated in the rearrangement (in 40E4-2-16-2.0, V_H-to-DJ_H rearrangement resulted in deletion of the D–J_H junction). We have therefore shown directly that the DJ_H units found in these fetal liver-derived A-MuLV transformants are intermediates in V_HDJ_H assembly, as had been suggested by the results of hybridization assays reported previously[13,14,23]. All six V_HDJ_H rearrangements characterized here have placed the V_H coding sequence out of frame with respect to the J_H coding sequence. This could reflect the small sample size or it could be that cells containing productive rearrangements are lost, perhaps through a toxic effect of free heavy chain[24].

We found no evidence for somatic point mutation. Comparison of the 200-base pair (bp) portion of the V_H81X sequence present in molecular clones of three V_HDJ_H recombinants (40E4-2-5-2.0, 40E4-2-16-2.0 and 22D6-G-1-2.1) with the germ-line sequence of the gene segment, and similar comparisons involving J_H segments, failed to reveal any nucleotide differences[18]. This is consistent with other evidence that rather than occurring coincidentally with rearrangement[25,26] somatic point mutation occurs principally at later stages in B-lymphocyte

Fig. 3 V_HDJ_H assembly in the 22D6-G A-MuLV transformant. ***A***, Primary and secondary rearrangement of the 3.0-kb J_H-containing *Eco*RI fragment from 22D6-G. Recombinant junctions were localized and sequence was determined as in Fig. 3. *a*, *b*, Partial nucleotide sequences of germ-line J_H3 (refs 3, 7) and $D_{SP2.3}$ (ref. 8) segments are shown. *c*, The sequence across the $D_{SP2.3}$–J_H3 junction found in clone 22D6-G-3.0. *d*, The 3′ terminal germ-line sequence of the V_H81X gene segment[18]. *e*, The sequence across the recombinant junction of clone 22D6-G-2.1; this recombinant is the result of rearrangement of V_H81X to the D–J_H3 fusion of 22D6-G-3.0. Symbols are defined in Fig. 2*A*. ***B***, Primary and secondary rearrangement of the 4.5-kb J_H-containing *Eco*RI fragment from 22D6-G. Recombinant junctions were localized and sequence was determined as in Fig. 3. *a*, *b*, Partial nucleotide sequences of germ-line J_H4 (refs 3, 7) and $D_{FL16.1}$ (ref. 8). *c*, Sequence of the $D_{FL16.1}$–J_H4 junction in clone 22D6-G-4.5. *d*, Partial sequence of the 22D6-G-2-3.5 recombinant, which was the product of recombination between a V_H segment and the DJ_H4 fusion of 22D6-G-4.5. Symbols are defined in Fig. 2*A*.

maturation that follow rearrangement. The consistent lack of somatic point mutation in rearrangements from the 40E4-2 line, which expresses TdT, implies that, contrary to a previous suggestion[27], the function of the enzyme in this line is not related to the process of generating somatic point mutants.

A role for TdT in the production of *N* regions[16] is strongly implied by the observation that *N* regions were present at four of six independent D–J_H or V_H–DJ_H junctions in the 40E4-2 line, which expresses TdT, but none was found among the four junctions examined in the 22D6-G line that lacks the enzyme.

An alternative hypothesis, that *N* regions are encoded by a set of germ-line genes, seems unlikely because of their extreme heterogeneity in length and sequence. Another argument against *N* regions being encoded stems from the observation that the *N*-region sequence GTGGGGGCC is found at the junction between D_{Q52} and J_H segments in the 18-81A-2 cell line[28]. The D_{Q52} segment is the most J_H-proximal *D* segment, occurring in the germ line about 700 bp to the 5′ side of J_H1. The nucleotide sequence from D_{Q52} to the J_H cluster has been determined previously[5]; this interval does not contain the 9-bp *N* region sequence of 18-81A-2. Thus, unless we invoke two acts of inversional recombination, so as to transpose a sequence originally 5′ to a site between D_{Q52} and J_H, we must conclude that the *N* region present at this D_{Q52}–J_H junction was not represented in the germ line. *N* regions are therefore likely to be synthesized *de novo* and TdT is likely the responsible enzyme.

We thank Keith Blackwell for advice and assistance in the isolation of the 22D6 rearrangements. S.V.D. is a fellow of the Jane Coffin Childs Memorial Fund for Medical Research. Fig. 4 Assay for terminal deoxynucleotidyl transferase by immunoprecipitation. TdT was assayed in metabolically labelled extracts from cell lines RL♂11 (lanes *a*, *d*), 22DG (lanes *b*, *e*) and 40E4-2 (lanes *c*, *f*), as described below. (Cell line 22D6 is the parent line from which clone 22D6-G was derived.) Immunoprecipitations were performed with normal rabbit serum (lanes *a*–*c*) or with rabbit anti-TdT antiserum (lanes *d*–*f*). The positions of molecular weight standards and their sizes ($\times 10^{-3}$) are indicated.

Methods: Cells (4×10^6) were labelled for 5 h at 37 °C in 2 ml methionine-free RPMI-1640 supplemented with 10% dialysed, inactivated fetal calf serum and 500 μCi ^{35}S-methionine. Cells were washed in PBS and lysed by addition of 1 ml RIPA buffer[34] containing 0.1 mM phenylmethylsulphonyl fluoride. Samples, containing 10^7 c.p.m. ^{35}S-labelled protein, were incubated with 5 μl normal rabbit serum for 1 h at 4 °C. Protein A-containing *Staphylococcus aureus* (25 μl of a 10% suspension) was added and incubation was continued for 30 min. Samples were cleared by centrifugation at 12,000*g* for 2 min. Precleared samples were incubated with 5 μl rabbit antiserum against calf TdT[35] or with 5 μl normal rabbit serum for 2 h at 4 °C. Protein A-containing *S. aureus* (25 μl of a 10% suspension) was added and incubation was continued for 30 min. RIPA buffer (1 ml) was added and samples were spun for 15 s at 12,000*g*. Pellets were washed twice with RIPA buffer. Immunoprecipitated protein was analysed by SDS-polyacrylamide gel electrophoresis and autoradiography.

A rhodopsin is the functional photoreceptor for phototaxis in the unicellular eukaryote *Chlamydomonas*

Rhodopsin is a visual pigment ubiquitous in multicellular animals. If visual pigments have a common ancient origin, as is believed, then some unicellular organisms might also use a rhodopsin photoreceptor[1,2]. We show here that the unicellular alga *Chlamydomonas* does indeed use a rhodopsin photoreceptor. We incorporated analogues of its retinal chromophore into a blind mutant; normal photobehaviour was restored and the colour of maximum sensitivity was shifted in a manner consistent with the nature of the retinal analogue added. The data suggest that 11-*cis*-retinal is the natural chromophore and that the protein environment of this retinal is similar to that found in bovine rhodopsin, suggesting homology with the rhodopsins of higher organisms. This is the first demonstration of a rhodopsin photoreceptor in an alga or eukaryotic protist and also the first report of behavioural spectral shifts caused by exogenous synthetic retinals in a eukaryote. A survey of the morphology and action spectra of other protists suggests that rhodopsins may be common photoreceptors of chlorophycean, prasinophycean and dinophycean algae. Thus, *Chlamydomonas* represents a useful new model for studying photoreceptor cells.

Chlamydomonas is an aquatic organism of 10 μm diameter with a single eye and two flagella[3] which together guide the swimming cell in its light environment. A coloured quarter-wave-layered eyespot focuses incoming light onto an overlying patch of plasma membrane containing ~10^5 receptor pigment molecules and also prevents light from passing through the cell to the receptor pigment[2]. As the cell rotates while swimming, its eye conically scans a pattern of light which modulates conductance changes that control the steering of its flagella, thus forming a simple, but nevertheless complete visual system. All the essential elements of the photoreceptor cells of a multicellular animal are present[2].

Although there are many light-sensitive pigments, particularly in protists[4], the receptor pigments in the eyes of all multicellular animals studied so far contain 11-*cis*-retinal as the chromophore; in addition, some freshwater fish and amphibians use 11-*cis*-3,4-dehydroretinal as a second chromophore. We used the following rationale to check for the presence of a retinal chromophore in *Chlamydomonas*. If a retinal moiety were the chromophore, replacing it by other retinal analogues would shift the action spectrum (the relative sensitivity of the cells to different wavelengths of light) compared with the natural pigment; such a shift in action spectrum would prove the incorporation and function of retinal. Nonspecific binding of retinals to protein would not produce the anticipated shifts. The behaviour used to test the photoreceptor response was that of phototaxis[2,5]—the swimming of an aquatic cell towards or away from light.

Numerous retinal analogues have been bound to bovine opsin and bacteriorhodopsin *in vitro*[6-9] to give pigments absorbing at different wavelengths of light. At least four analogues have recently been shown to shift the behavioural action spectrum of *Halobacterium*[10,11] and a similar rationale using a riboflavin analogue was applied to determine the nature of the chromophore for phototropism in the fungus *Phycomyces*[12].

As with the *Phycomyces* studies in which a riboflavin auxotroph was used[12], we used a blind mutant incapable of synthesizing retinal in the dark to measure incorporation of analogues. As any mutant blocking carotenoid synthesis would also block retinal synthesis, we surveyed all carotenoid mutants we could obtain; as hypothesized, these are blind compared with wild type. We chose the mutant FN68 (Car-1) because of the comparative slowness of its light induction of carotenoids (K.W.F *et al.*, in preparation) and its 1,000–10,000-fold increased threshold sensitivities relative to wild type (compare Fig. 1*B*, *C* with *D*). The carotenoid biosynthesis of the mutant[13] is blocked in the dark at a step before phytoene. The mutant is negatively phototactic, that is, it normally swims away from light. The wild type (for carotenogenesis) (Car$^+$ *agg*$^-$ cell, designated FN13) was a negatively phototactic strain (derived from culture 806 of *Chlamydomonas reinhardtii* 137c(−); given by Robert Smyth).

We used threshold measurements of phototaxis (Fig. 1) to determine the sensitivity of the cells to a particular colour of light. The sensitivity or reciprocal of the threshold was plotted as a function of wavenumber (wavelength^{-1}) to give a phototaxis action spectrum for each analogue tested (Fig. 2*A*, *a*–*g*). Peaks were determined by fitting the data to a standard curve[14]. As in other animals, *trans*-retinol (vitamin A) and β-carotene function as well as retinal, while retinoic acid has no effect.

To provide a standard to determine the effect of the protein environment on a retinal analogue, a simple reference environment was needed. As it is known that the retinal in other rhodopsins is attached to the protein as a protonated Schiff base (SBH$^+$), the absorption of the analogue in that form, attached to a small compound such as *n*-butylamine in the solvent methanol, provides a useful reference. The difference (in wavenumber) between the absorption maximum of SBH$^+$ in methanol and those of the pigments has been defined as the opsin shift[15]. The action spectra maxima for *Chlamydomonas* are not only shifted towards the red away from the reference maxima provided by the protonated Schiff bases (SBH$^+$), but the trends of these opsin shifts (Fig. 3) are very similar to those encountered for bovine rhodopsins. The opsin shifts from the SBH$^+$ model vary over a narrow range, with the 9-*cis* analogues having a smaller opsin shift than the 11-*cis* analogues. In contrast, the shifts observed here are markedly different from those encountered with bacteriorhodopsin, which, unlike visual pigments, absorb at 570 nm and only accept *trans*- and 13-*cis*-retinals[16]. The natural or light-induced action spectra maximum for *Chlamydomonas* is at 503 nm, whereas the maxima resulting from *trans*- and 11-*cis*-retinal incorporation are at 505 and 501 nm, respectively (Fig. 2). As these values are within experimental error, it is likely that the retinals are isomerized in the dark (to 11-*cis* by an isomerase?). However, the maximum at 488 nm caused by incorporation of 9-*cis* is outside the range of error and parallels the 485 nm maximum of bovine 9-*cis* rhodopsin. These findings suggest that *Chlamydomonas*, a chlorophycean, has a pigment homologous to bovine rhodopsin. We suspect the existence of rhodopsins in other algae also (Fig. 4). These pigments show a variation in their maximum absorption wavelength, from 457 to 493 nm, which implies a similar variety of chromophore environments to those in multicellular animals. Although they are probably all rhodopsin-like pigments, the nature of the chromophores in the Prasinophyceae and Dinophyceae remains to be proven.

Our results involving incorporation of retinal analogues have established *Chlamydomonas* as a viable model for studies of rhodopsin photoreceptors. A major advantage of this system is that it is already widely used for the study of basal bodies[17], circadian rhythms[18,19] and flagellar architecture and function[20,21,38], among others. Furthermore, the visual pigment and ionic processing elements are readily accessible as they lie in the plasma membrane at the surface of the cell. The versatility of this genetically well-studied microorganism for the study of photoreception, together with the apparent close homology of its photoreceptor cells to those of multicellular organisms, make it an excellent model. Use of this simple unicellular system

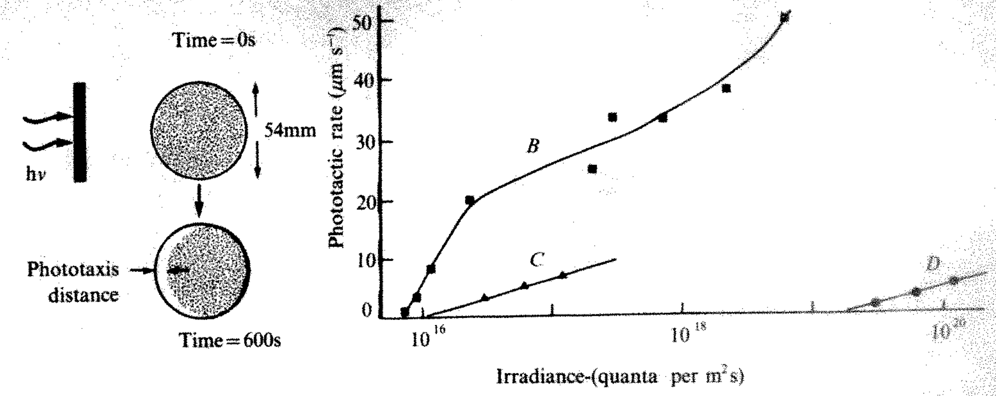

Fig. 1 *A*, The experimental set-up at time 0 and at 600 s. *B–D*, Dose–response curves, using 540 nm light with: *B*, FN13 cells (normal for carotenoids); *C*, FN68 cells and added 11-*cis*-retinal (25 μM); and *D*, FN68 cells without any added retinal.

Methods: FN68 cells were taken from slant cultures and grown on plates (salt, acetate Bacto-tryptone media with no yeast)[23]. These cells were transferred to HSM liquid (9.3 mM NH_4Cl, 81 μM $MgSO_4$, 0.1 mM $CaCl_2$, 8.27 mM K_2HPO_4, 5.3 mM KH_2PO_4, 15 mM Na acetate, plus trace elements[24]) and grown for 5–7 days in the dark at 18 °C. These vegetative cells were converted to gametes by nitrogen starvation in NMM (81 μM $MgSO_4$, 0.1 mM $CaCl_2$, 4.13 mM K_2HPO_4, 2.65 mM KH_2PO_4, plus trace elements[24]). On the day before the experiment, vegetative cells were centrifuged out at 1,500 r.p.m. for 3 min. The pellets were washed two or three times with NMM and resuspended in NMM to a concentration of $5\text{–}7\times10^6$ cells ml^{-1}. To the final NMM and cell suspension 25 μM of each retinal analogue and 0.025% α-tocopherol (as an antioxidant) were added. There was a dose-related effect of the analogues, and 25 μM was the lowest concentration that resulted in nearly full recovery with the most effective analogues. All analogues were transferred to methanol solvent immediately before addition to the cells. α-Tocopherol was also dissolved in methanol. The final concentration of methanol in the cell suspension was always <0.5%. Cells were left overnight for gametes to develop and incorporate the analogues. All cells were checked for motility and bacterial contamination. 4–5 ml of the cell suspension were poured into 54 mm diameter polystyrene Petri plates and placed at various distances from a stabilized quartz-iodide light source, the colour of which was selected with a series of interference filters. As the same set of filters was used for each analogue, the error in the comparative data is very small. To ensure a high degree of accuracy, two interference filters in series were used on the rapid fall-off in response to the red. Each light condition was measured with a 400 series Photodyne radiometer calibrated to ±5% for each wavelength. The energies were converted to absolute irradiances and corrected for the small amount of plate absorption. To measure action spectra, dose–response curves of phototactic rate versus light intensity were obtained. The distance travelled by the trailing edge of phototactic cells was measured for a 600-s period. Any effects of light scattering were minimized as light passed through the clear region created by cells swimming away from the light. The amount of opsin available may differ from day to day and the absolute sensitivity at all wavelengths may be changed; therefore, a complete action spectrum for one analogue was determined for one set of cells in one day. A control (undoped cells) was always included and measured for phototactic threshold. The procedure was repeated on a second or third day, if necessary, and all data points plotted with a common symbol for each day's set of data, as shown in Fig. 2. Unfortunately, in our mutant some induction of carotenoid and retinal synthesis (K.W.F. *et al.*, in preparation) occurs in the dark in the presence of retinals and retinal oxidation products (as also found in *Phycomyces*)[25]. However, we minimized oxidation by limiting exposure to light and oxygen and we added the analogues in optimum amounts; thus chemical induction did not interfere with out experiments. The slopes of the dose–response curves vary with wavelength as the conical scanning mechanism (see ref. 2 for details) results in a signal proportional to the magnitude of contrast modulation, which varies with wavelength. Therefore, we used the threshold for phototaxis rather than the intensity to give a standard response. Using this method, the presence of low concentrations of analogues, which contribute <0.001 absorbance units to the contrast modulation, has no effect on the action spectra. For threshold, we used the linear extrapolation to zero response, on a linear plot of phototactic rate as a function of the log of light intensity.

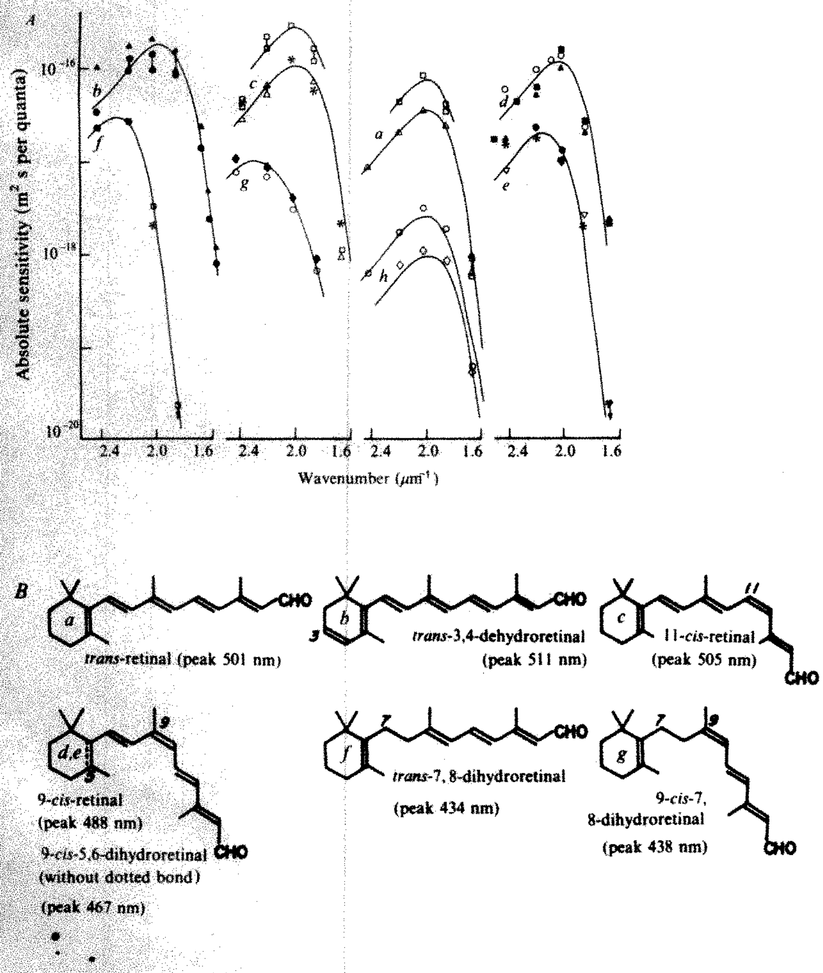

Fig. 2 *A*, The action spectra for different incorporated analogues. *B*, The structure and excitation maxima of the analogues: *a*, *trans*-retinal (peak 501 ± 5 nm); *b*, *trans*-3,4-dehydroretinal[26] (peak 511 ± 2 nm); *c*, 11-*cis*-retinal (peak 505 ± 6 nm); *d*, 9-*cis*-retinal (with dotted bond) (peak 488 ± 5 nm); *e*, 9-*cis*-5,6-dihydroretinal[27] (without dotted bond) (peak 467 ± 5 nm); *f*, *trans*-7,8-dihydroretinal[27] (peak 434 ± 3 nm); *g*, 9-*cis*-7,8-dihydroretinal[27] (peak 438 ± 5 nm); and *h*, light induced at 540 nm for 1.8×10^3 s at an irradiance of 4.2×10^{19} quanta per m^2 per s (upper curve) and 2.5×10^{19} quanta per m^2 per s (lower curve) (peak 503 ± 2 nm).

Methods: The action spectra were determined by the method described in Fig. 1 legend. log of sensitivity (reciprocal of threshold) on an absolute scale is plotted on the ordinate as a function of the wavenumber (wavelength^{-1}) (μm^{-1}, 10,000 cm^{-1}); when plotted in this way, the shape of the curve of rhodopsin excitation does not change despite shifts of maxima. The ordinate is given an absolute scale to compare the sensitivities of each analogue added at the same concentration. The absolute sensitivity of an analogue is a function of its affinity and quantum efficiency; we did not distinguish between these two parameters in this study. In some cases a second partial curve is drawn through a particular day's data because on that day the analogue's own absolute sensitivity was different. The data were fitted to a standard rhodopsin curve[14] (solid lines) and from this fit the peak wavelengths were obtained. The one exception is 9-*cis*-7,8-dihydroretinal (*g*) for which the curve is distorted by competition with the induced native chromophore (K.W.F. *et al.*, in preparation). To obtain the best estimate of the maxima of the data curve, however, a 1/6 component of natural chromophore was subtracted and the standard curve fitted to the result. In all other cases we are confident of complete dominance of the substitution.

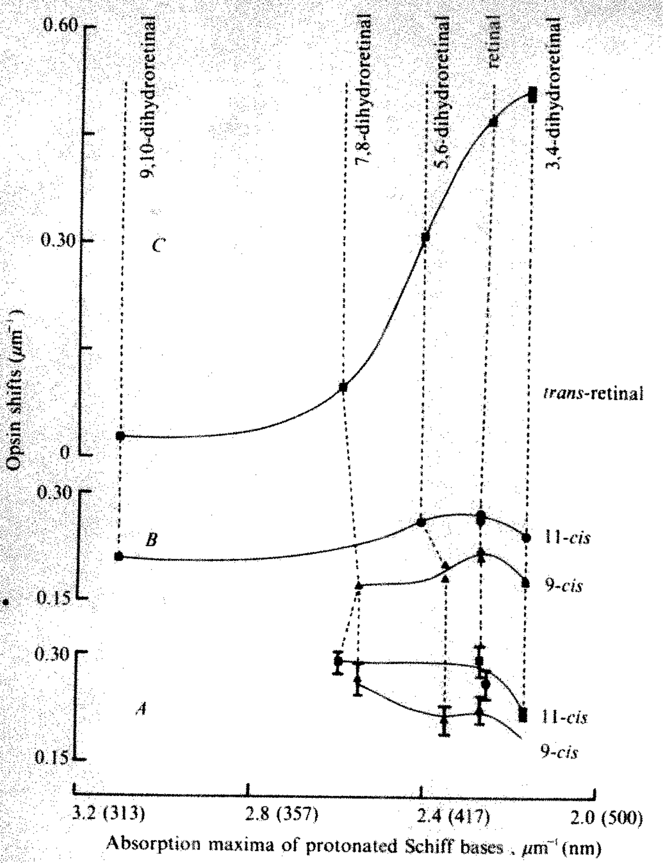

Fig. 3 Chromophore environments of *Chlamydomonas* rhodopsin (*A*), bovine rhodopsin (*B*) and bacteriorhodopsin (*C*). Retinal chromophores in rhodopsins are bound to opsin via a protonated Schiff base linkage, absorption maxima being considerably redshifted from those (in methanol) of protonated Schiff bases formed with *n*-butylamine (SBH^+). This redshift, reflecting the unique rhodopsin protein environment of retinal, expressed in wavenumbers (μm^{-1}, 10,000 cm^{-1}), is defined as the opsin shift[15]. Retinals nonspecifically bound to proteins in the SBH^+ form absorb at the SBH^+ wavelength[28], and in free solution in the UV. In *Chlamydomonas* the action spectra are again redshifted from the SBH^+ form and are fitted so well to the standard rhodopsin curve, so nonspecific protein attachment of retinals has no effect on phototaxis. For *Chlamydomonas* rhodopsin we define opsin shift to include the difference between the maxima of SBH^+ and those of its action spectra. An analogue added *trans* will probably be isomerized by the cell to 11-*cis*, but the SBH^+ values are nearly identical. Opsin shifts of the excitation maxima of *Chlamydomonas* phototaxis (*A*) and of absorption maxima of bovine rhodopsins (*B*) and bacteriorhodopsin (*C*) resulting from incorporation of various analogues are plotted against maxima of the corresponding SBH^+, expressed in μm^{-1}. Data points in the 9-*cis* (▲), 11-*cis* (●) and *trans* (■) series are connected laterally for clarity. The vertical dashed lines interconnect the double bond isomers of respective retinals. The values for the excitation maxima of *Chlamydomonas* are listed in Fig. 2 legend. The values for absorption maxima of SBH^+, bovine rhodopsins (RH) and bacteriorhodopsins (BR) are as follows: *trans*-retinal (*a* of Fig. 2*B*), SBH^+ 443 nm (ref. 29), BR 560 nm (ref. 15); *trans*-3,4-dehydroretinal (*b*), SBH^+ 460 nm (ref. 28), BR 603 nm (ref. 30) or 599 nm (ref. 31); 11-*cis*-3,4-dehydroretinal, SBH^+ 460 nm (assumed to be like *trans* as only a few nanometres different)[28], RH 517 nm (ref. 28); 9-*cis*-3,4-dehydroretinal, SBH^+ 460 nm (assumed to be like *trans*), RH 501 nm (ref. 28) or 500 nm (ref. 32); 11-*cis*-retinal (*c*), SBH^+ 440 nm (ref. 15), RH 498 nm (ref. 28) or 500 nm (ref. 15); 9-*cis*-retinal (*d*), SBH^+ 440 nm (ref. 15), RH 485 nm (ref. 15) or 487 nm (ref. 28); *trans*-5,6-dihydroretinal, SBH^+ 415 nm (ref. 28), BR 476 nm (ref. 15); 11-*cis*-5,6-dihydroretinal, SBH^+ 415 nm (assumed to be like *trans*), RH 465 nm (ref. 28); 9-*cis*-5,6-dihydroretinal (*e*), SBH^+ 425 nm (ref. 15), RH 465 nm (ref. 28) or 460 nm (ref. 15); *trans*-7,8-dihydroretinal (*f*), SBH^+ 385 nm (ref. 15), BR 400 nm (ref. 15); 9-*cis*-7,8-dihydroretinal (*g*), SBH^+ 392 nm (ref. 33), RH 420 nm (ref. 15); and *trans*-9,10-dihydroretinal, SBH^+ 322 nm (ref. 15), RH 345 nm (ref. 15), BR 325 nm (ref. 15).

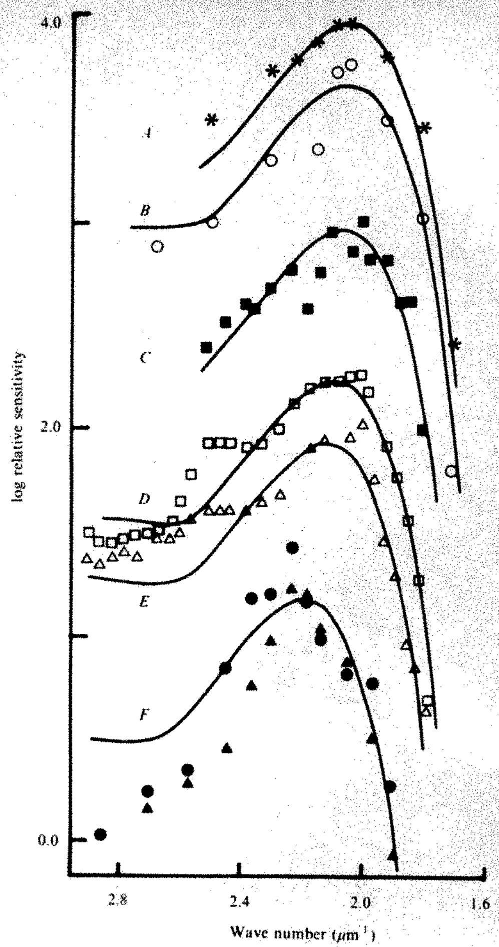

Fig. 4 Action spectra of algae taken from the literature. The most probable homologous characteristic to identify between alga eyes and those of multicellular organisms is an oriented rhodopsin-like protein formed in the plasma membrane regulating ion currents. The use of a photoreceptor at the quarter-wave position overlying a quarter-wave stack antenna in several algal classes (see ref. 2 for details) requires an oriented receptor for optimal functioning. On the grounds of morphology and action spectra, therefore, we have redrawn several action spectra from the literature: log of sensitivity (reciprocal of threshold or quantum efficiency) is plotted as a function of the wavenumber (wavelength^{-1}) (μm^{-1}, 10,000 cm^{-1}) as in Fig. 2*A*. To facilitate comparison, the data have been arbitrarily displaced on the ordinate and the same standard curve[14] has been horizontally shifted to best fit the data from the maximum to the red cut-off of sensitivity. We anticipate significant distortion in the action spectra above 2.3 μm^{-1} (to the violet side of 430 nm) due to activation of photosynthesis. *A*, The 'stop' response (*) of *Volvox aureus* (a chlorophycean) (peak 493 nm)[34]; *B*, the threshold positive phototaxis response (○) of *V. aureus* (peak 490 nm)[34]; *C*, the photoreceptor electrical potential (■) of *Haematococcus pluvialis* (a chlorophycean) (peak 483 nm)[35]; *D*, the threshold negative phototaxis response (□) of *Platymonas subcordiformis* (a prasinophycean) (peak 478 nm)[36]; *E*, the threshold positive phototaxis response (△) of *Pl. subcordiformis* (peak 472 nm)[36]; *F*, the stop response (▲) and positive phototaxis (recalculated) (●) of *Gymnodinium splendens* (a dinophycean) (peak 457 nm)[37].

should allow us to elucidate the active sites of protein interaction; transduction aspects; adaptation; signal processing; membrane, receptor and chromophore biosynthesis and maintenance; nutritional effects on the lipid environment of the receptor; and effects of cell homeostasis.

The use of eukaryotic rhodopsins as visual receptors may indeed be quite ancient and as common in several classes of algae as in higher animals. The use of molecular biology[22] to check for homology between the rhodopsins found throughout these algae and higher animals should prove exciting. •

We thank Dr Robert D. Smyth for discussions and the important suggestion that a rhodopsin might be the photoreceptor in *Chlamydomonas*. We also thank the NIH for support (grant EY 03760 to K.W.F. and N.P. and grant EY 01253 to K.N.) and the many who lent us equipment to make these experiments possible. W.-Y. Wang (University of Iowa) supplied the FN68 mutant.

Co-localization of neurotensin-like immunoreactivity and ^{3}H-glycine uptake system in sustained amacrine cells of turtle retina

Reto Weiler* & Alexander K. Ball

Department of Anatomy and Lion's Sight Centre, Faculty of
Medicine, The University of Calgary, Calgary, Alberta,
Canada T2N 4N1

Amacrine cells are axonless intrinsic neurones of the vertebrate retina which have cell bodies in the proximal inner nuclear layer and processes contributing to the synaptic network of the inner plexiform layer. They receive input from bipolar, interplexiform and other amacrine cells, and synapse onto these and ganglion cells[1,2]. Amino acid and monoamine transmitters are found in most retinal neurones[3], but peptide transmitters are exclusively located in amacrine cells[4]. Only one neuropeptide, amino acid or monoamine transmitter exists in any single amacrine cell population[4,5]. Coexistence of neuropeptides with classical transmitters has been demonstrated histologically in many neurones of the central nervous system[6], but the physiological relevance of these findings is unknown[7]. We report here evidence of such coexistence in retinal amacrine cells of the turtle, *Pseudemys scripta elegans*. Using combined immunocytochemistry and autoradiography, we have localized both neurotensin-like immunoreactivity and a high affinity uptake system for ^{3}H-glycine to the same amacrine cell, implying that this cell type may use both substances as neurotransmitters. We also present electrophysiological evidence that this type of amacrine cell responds to photic stimulation with a sustained and graded membrane depolarization.

We examined formalin-fixed frozen sections of turtle retina by the peroxidase-antiperoxidase method[8] and found neurotensin-like immunoreactivity in four different amacrine cell types (Fig. 1*a–d*)[9,10]. Two of these types occurred more frequently (Fig. 1*a*, *b*) than the other two (Fig. 1*c*, *d*). Type A cells (Fig. 1*a*) are large, with the soma located in the first row of amacrines. They sent a single primary process to the middle of the inner plexiform layer before branching in the proximal half of this layer. Type B cells (Fig. 1*b*) are smaller, with the soma located in the first or second row of amacrines. They stain much more intensely than type A cells. Beaded processes from type B cells extend along the inner nuclear-plexiform layer border for a short distance before dropping to the proximal half of the inner plexiform layer. Both cell types are identical to other neurotensin-like immunoreactive cells described recently[11]. Less frequent neurotensin-like immunoreactive cell types were found in the distal half of the inner plexiform layer (large pyramidal soma, Fig. 1*c*) and the ganglion cell layer, where a thick primary process extended into the middle of the inner plexiform layer before branching (Fig. 1*d*).

Somas of varying sizes in different rows of the inner nuclear layer accumulated ^{3}H-glycine (Fig. 1*e*). Labelling of the inner plexiform layer was diffuse, with no evident banding pattern. Some of the somas which accumulated ^{3}H-glycine also showed neurotensin-like immunoreactivity. We identified these somas as type B cells on the basis of their shape, location and the distribution of their processes. (Somas of type A cells are characterized by their single process, which does not branch until it reaches the proximal inner plexiform layer, whereas type B somas are characterized by several processes which branch immediately after leaving the soma; Fig. 1*a*, *b*.) The diffuse labelling pattern of ^{3}H-glycine uptake within the inner plexiform layer corresponds well with the branching pattern of type B cells. In thin sections (0.5 μm), the co-localization of the two markers in a type B soma was readily identifiable (Fig. 1*f*). Such preparations also confirmed that ^{3}H-glycine uptake and neurotensin-like immunoreactivity was co-localized in type B but not in type A cells (Fig. 1*f*). Although type B cells all accumulate ^{3}H-glycine, they make up only 7% of the ^{3}H-glycine-accumulating cells in the turtle retina. The co-localization of these two markers in one cell implies that this neurone uses both an amino acid and a neuropeptide as neurotransmitters. We also investigated the possible co-localization of neurotensin-like immunoreactivity with [^{3}H]-γ-aminobutyric acid and dopamine accumulation, but evidence of such coexistence could not be established.

In parallel experiments we used intracellular recording and staining techniques to examine the function of type B cells. The processes of most injected amacrine cells ($n = 47$) were either mono- or multi-stratified within the inner plexiform layer, covering 10–70% of it in transverse sections. This branching pattern differed in cells of only one group ($n = 6$), which had somas located in the proximal inner nuclear layer. A few processes from cells of this smaller group left the soma close to the inner nuclear-plexiform layer border, descending through the total inner plexiform layer and branching at different levels with an increasing density of fine branches in the proximal half (Fig. 2*a*). The six injected cells of this type were morphologically homogeneous, differing from one another only in the size of their receptive field. The size and location of the soma of these cells, and the diffuse pattern of their process distribution within

---

* Present address: Zoological Institute, University of Munich, Luisenstrasse 14, 8 Munich 2, FRG.

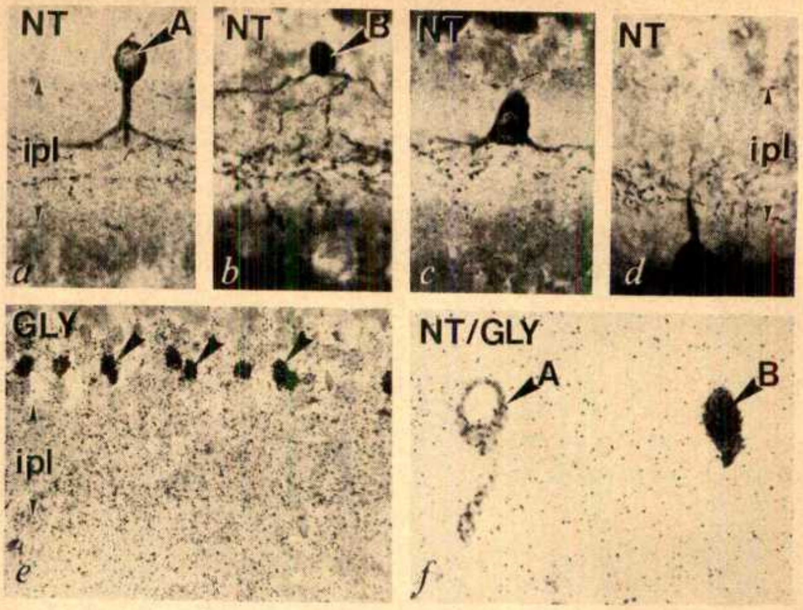

Fig. 1 *a*, Neurotensin (NT)-like immunoreactivity in a large amacrine cell of the turtle retina (A). A single primary process distributes fibres to the proximal half of the inner plexiform layer (ipl). Neurotensin-like immunoreactivity was localized using primary rabbit antiserum against neurotensin (dilution 1:1,000), goat anti-rabbit γ-globulin (Sigma) (dilution 1:20) and rabbit peroxidase-antiperoxidase complex (Miles) (dilution 1:50). Background staining was reduced with the addition of 1% normal goat serum (Sigma) to all reagents. *b*, Neurotensin-like immunoreactivity in a small amacrine cell of the turtle retina (B). Numerous processes distribute fibres to the proximal half of the inner plexiform layer. *c*, Neurotensin-like immunoreactivity in an interstitial cell of the turtle retina. The soma occupies the distal half of the inner plexiform layer and processes ramify in its proximal half. *d*, Neurotensin-like immunoreactivity in a displaced amacrine cell. A single primary process distributes fibres to the proximal half of the inner plexiform layer. *e*, Autoradiograph showing ^{3}H-glycine accumulation by several turtle amacrine cells (arrowheads). Labelling of the inner plexiform layer is diffuse. The section was overexposed (2 weeks) to emphasize glycinergic neurones and slightly counterstained with toluidine blue. *f*, Combined immunocytochemistry-autoradiography of neurotensin and ^{3}H-glycine uptake. Neurotensin-like immunoreactivity in the two major cell types encountered in turtle retina is indicated (A, B). Autoradiographic label is present over the type B cell showing that it also has a high affinity uptake system for glycine. The type A cell is not labelled. The section was exposed for 1 week and is not counterstained. *a*–*e*, ×318; *f*, ×650. Thickness of sections: *a*–*d*, 40 μm; *e*, *f*, 0.5 μm.

Methods: For combined autoradiography and immunocytochemistry, turtles (20 cm shell diameter) were injected with 25 μl ^{3}H-glycine (NEN), resulting in an estimated concentration of 3 μM at the retinal level. After 4 h, the retinae were fixed and processed for immunocytochemistry according to published procedures[18]. 40 μm-thick sections of resin-embedded retinae were used to localize neurotensin-like immunoreactive neurones and these sections were then re-cut at 0.5–2 μm[19] for autoradiography. Intracellular microelectrodes filled with Lucifer yellow or horseradish peroxidase were used to record intracellularly from amacrine cells in an eye-cup preparation. The histological procedures after dye injection were similar to those described elsewhere[9,20].

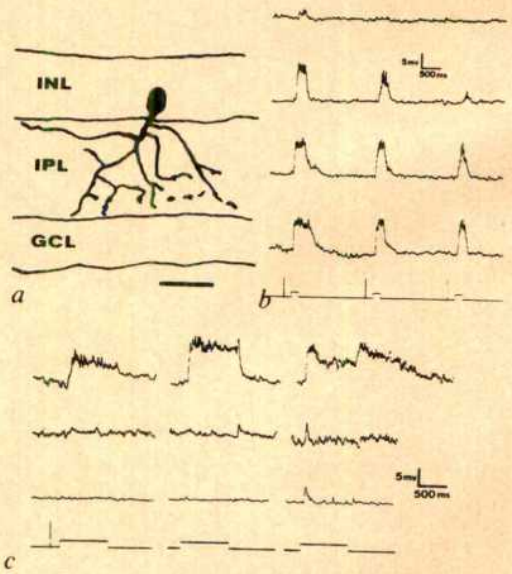

Fig. 2 *a*, Camera lucida drawing from transverse sections of an amacrine cell stained intracellularly with Lucifer yellow. Processes leave the soma close to the inner nuclear-plexiform layer border and ramify mainly in the proximal half of the inner plexiform layer. Scale bar, 25 μm. *b*, Photoresponses of the same cell to white light stimulation from a quartz-iodine lamp of increasing intensity (from left to right: 1.6×10^{-2}, 1.6×10^{2} erg s^{-1} cm^{-2}) and different size (from top to bottom: small spot 500 μm diameter, large spot 3,500 μm, annulus 3,500/1,200 μm). The signals were amplified with a WPI 707 amplifier and stored on a Racal tape recorder. *c*, Photoresponses of the same cell to different monochromatic stimuli (small spot, from left to right: 625, 530, 450 nm). The irradiance was attenuated from top to bottom by 6, 4, 3 and 2 log units. The photoresponses are univariant with maximal sensitivity at 625 nm.

the inner plexiform layer, was identical to that of type B cells. They responded to light at the centre of their receptive fields with graded depolarizations (Fig. 2*b*). This depolarization was most prominent with a spot diameter of 500 μm and with the light intensity attenuated by 2.5 log units. Repetitive oscillations varying over 1–5 mV shaped the response. The centre response, including the oscillations, could be abolished almost completely by increasing the diameter of the illuminated area by up to 1,000 μm to stimulate both the centre and periphery of the cell's receptive field (middle trace, Fig. 2*b*). The persistence of only small 'on' or 'off' responses, depending on the light intensity, suggested the presence of an antagonistic surround, but peripheral illumination by itself generally produced no response. Monochromatic illumination evoked univariant responses (Fig. 2*c*), with maximal sensitivity around 625 nm. These physiological properties are similar to those attributed to diffuse amacrine cells described elsewhere[9].

Our co-localization of neurotensin-like immunoreactivity and ^{3}H-glycine uptake may indicate that these two putative neurotransmitters, a neurotensin-like peptide and glycine, are released from the synaptic endings of type B cells in the inner plexiform layer. As such cells appear to be sustained-depolarizing amacrines with diffuse arborizations in the inner plexiform layer, these transmitters should be released in both distal and proximal levels (sublaminae a and b) of the layer during depolarization induced by illumination of the receptive field centre.

We do not yet have evidence for a physiological action of both glycine and neurotensin in the turtle retina. In the mudpuppy retina, however, glycine inhibits both on and off ganglion cells, whereas neurotensin excites these cells[12,13]. Because the dendrites of off-centre ganglion cells usually ramify in inner plexiform layer sublamina a and those of on-centre ganglion cells usually ramify in sublamina b[14–16], focal illumination should activate both neurotensin- and glycine-responsive mechanisms in both on- and off-centre ganglion cells. The electrophysiological findings in the mudpuppy retina are therefore in good agreement with the assumption of a release by a diffuse amacrine cell of neurotensin and glycine in both sublaminae.

If release and action of neurotensin and glycine within the turtle inner plexiform layer proves widespread, this would pose interesting questions about the role of neurotransmitters in visual information processing. Co-release as well as co-content of a peptide and a cooperatively acting conventional transmitter has been demonstrated elsewhere[17], but co-release of antagonistic transmitters is unprecedented. The type B amacrines may be capable of multiple actions on postsynaptic neurones in the inner plexiform layer. This may enable a simple pathway to create a complex response pattern in postsynaptic neurones, thus considerably increasing the functional potentialities of the neural network of the inner plexiform layer.

This work was carried out in the laboratories of Dr William K. Stell. We thank Dr Stell for criticism of this work and for reading the manuscript. This work was supported by grants to W. K. Stell and A.K.B. from the MRC of Canada, W. K. Stell, A.K.B. and R.W. from the Alberta Heritage Foundation for Medical Research and to R.W. from the Swiss Academy of Medicine.

Interactions between enkephalin and GABA in avian retina

Carl B. Watt, Ying-yet T. Su & Dominic Man-Kit Lam

Cullen Eye Institute, Baylor College of Medicine,
Houston, Texas 77030, USA

In addition to conventional neurotransmitters such as acetylcholine, dopamine, glycine and γ-aminobutyric acid (GABA)[1,2], a number of peptide-immunoreactive substances have recently been localized in the vertebrate retina[3,4]. The functional roles of these retinal peptides and their interactions with conventional neurotransmitters are largely unknown. We have previously shown that exogenous opiates affect both the release of GABA and the firing patterns of ganglion cells in the goldfish retina[5], and we have now begun a systematic characterization of the opioid pathways in the chicken retina, because, among vertebrate retinas, avian retinas contain the highest concentration of enkephalins[6]. Monoclonal antibodies specific for enkephalin have been used to demonstrate that a subpopulation of enkephalin-containing amacrine cells exists in the chicken retina[6,7]. This retina also synthesizes Met^5-enkephalin and releases it on cell depolarization[6,8,9]. The enkephalin-induced inhibition of GABA release in goldfish retina[5] led us to examine whether similar interactions occur in chicken, and if so, whether enkephalins and GABA coexist in the same amacrine cells. Our results, presented here, indicate that exogenous enkephalins do indeed inhibit GABA release in the chicken retina. Surprisingly, we found that although some amacrine cells contain both enkephalin and GABA, others contain only one or the other.

The effect of opiates on K$^+$-stimulated release of pre-loaded GABA from GABA-accumulating amacrine cells of the chicken retina was examined by a method reported earlier[5,10,11]. As exogenous GABA is taken up by both horizontal cells and subpopulations of amacrine cells in the retina[12], the amount of ^{3}H-GABA accumulated into GABAergic horizontal cells was minimized by injecting ^{3}H-GABA directly into the vitreous humour of the eye *in situ*[11,12]. After 1 h, over 90% of the accumulated ^{3}H-GABA was localized in GABA-accumulating amacrine cells (C.B.W., Y.-Y.T.S. and D.M.-K.L., unpublished result; see also ref. 11). The release of ^{3}H-GABA from these cells by elevated external K$^+$ (50 mM) in the absence or presence of opioid analogues could then be measured in isolated retina[5]. Met^5-enkephalin inhibits K$^+$-stimulated release of ^{3}H-GABA in a dose-responsive manner (Fig. 1). This inhibition is mimicked by the enkephalin analogue [D-Ala^2,D-Leu^5]enkephalin (DADLE) and the opioid agonist morphine, but is reversed by the opioid antagonist naloxone. The maximal inhibition of ^{3}H-GABA release by an opiate we tested was ~40%.

A logical extension of this study was to examine the anatomical relationships between putative enkephalinergic and GABAergic amacrine cells in this retina. A direct approach was to visualize enkephalinergic and GABA-accumulating neurones in the same retinal section. We used immunocytochemistry of enkephalin immunoreactivity to visualize the enkephalinergic neurones[5,13-16]. The putative GABAergic neurones were localized by ^{3}H-GABA uptake *in vitro* followed by autoradiography, an appropriate choice as in other retinae we have shown that neurones possessing a high-affinity mechanism for GABA uptake also contain the enzyme for GABA biosynthesis, and are therefore likely to be GABAergic[17,18]. Thus, it is reasonable

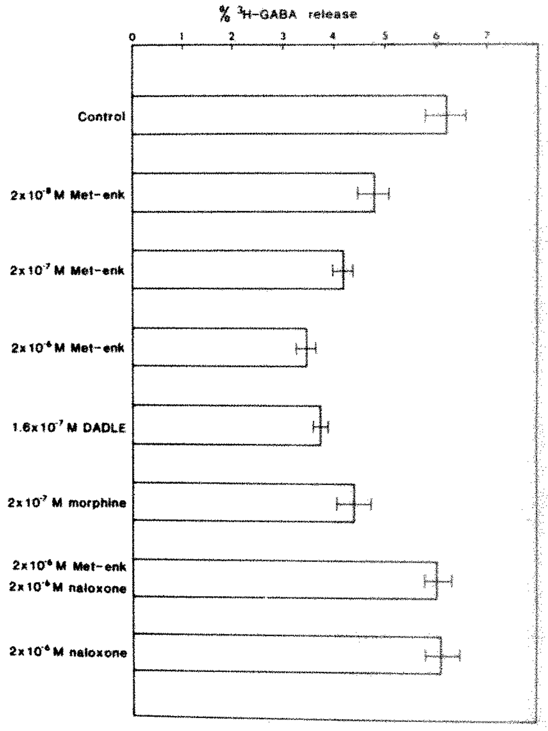

Fig. 1 Effects of opioid agonist and antagonist on K$^+$-stimulated ^{3}H–GABA release from GABA-accumulating amacrine cells of the chicken retina. One hour after an intravitreal injection *in vivo* with 50 μl Ringer's solution containing 40 μCi ^{3}H-GABA (specific activity 82.6 Ci mmol^{-1}), the injected eye was removed and the posterior eye cup bisected. The two pieces of retina were washed with excess oxygenated Ringer's solution for 30 min then incubated for 3 min with 1.5 ml of normal or K$^+$-rich (50 mM) Ringer's solution in the absence or presence of an opioid analogue, using a method previously described. The figure shows the percentage of ^{3}H-GABA released (radioactivity released/radioactivity present in the retina) in different conditions. Each bar represents the mean ± s.e.m. from at least three independent experiments of duplicate samples.

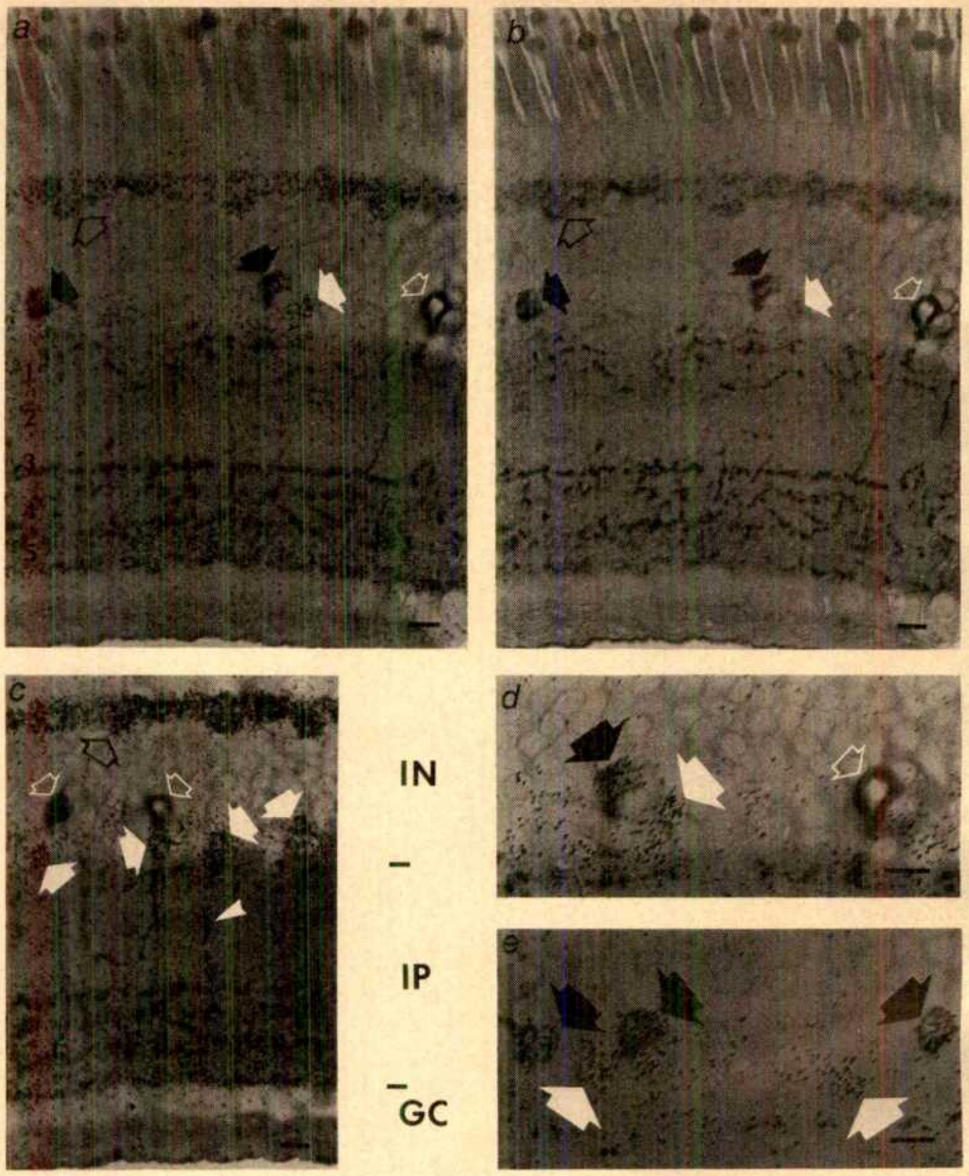

Fig. 2 Simultaneous localization of enkephalins (by immunocytochemistry) and ^{3}H-GABA uptake (by autoradiography) in the chicken retina. *a*, *b*, GABA-accumulating horizontal cells in chicken retina do not contain enkephalins. Double-labelled cells are denoted by solid black arrows; solid white arrows and open white arrows indicate cells labelled only for GABA or enkephalin, respectively. Open black arrows denote GABA-labelled horizontal cells. In *c* the white arrowhead indicates a GABA-labelled process within the inner plexiform (IP) layer. *d*, A higher magnification of the labelled cells in *a*. *e*, A higher magnification demonstrating typical double-labelled cells. IN, inner nuclear layer; GC, ganglion cell layer; 1–5 denotes distal to proximal sublayers of IP. Scale bar, 10 μm.

Methods: To visualize enkephalin-immunoreactive cells and GABA-accumulating neurones in the same retinal section, the retina was processed sequentially for autoradiography and immunocytochemistry. A piece of retina was isolated under room light and incubated for 10 min in 100 μl of an oxygenated Ringer's solution containing 10 μCi ^{3}H-GABA (specific activity 82.6 Ci mmol^{-1}). After incubation, the retina was rinsed for 1 min in unlabelled saline and placed in a cold fixative (4% parformaldehyde/0.1% glutaraldehyde in 125 mM phosphate buffer, *p*H 7.3) for 1 h and transferred to a fresh fixative (4% paraformaldehyde) overnight at 4 °C. Transverse sections (75 μm thick) of the ^{3}H-GABA–labelled retina were then cut with a vibratome and processed for enkephalin-immunoperoxidase staining at the light microscopic level. All steps were performed at room temperature and antibodies were diluted in phosphate-buffered saline (PBS, 20 mM phosphate buffer, 0.9% NaCl, *p*H 7.3) with 0.3% Triton X-100. Sections were first washed in 4% goat serum for 1 h, then incubated overnight in the primary antiserum (rabbit anti-Leu^5-enkephalin; batch A-206 from K.-J. Chang[6,15]) at a dilution of 1:1,000. After the incubation, the retinal sections were washed three times for 10 min with PBS and incubated in goat anti-rabbit IgG (1:20) for 3 h. After washing twice for 15 min in PBS, the sections were incubated in rabbit peroxidase–antiperoxidase (1:50) for 3 h, rinsed twice for 15 min in PBS, then transferred to the staining solution (10 ml PBS, 100 μl H_2O_2, 30 μg diaminobenzidine 4-HCl) for 4–7 min. After the post-staining wash and light microscopic examination, the sections were fixed overnight with 2% glutaraldehyde in 125 mM phosphate buffer. Retinal sections were subsequently embedded in plastic[13], and autoradiograms prepared routinely according to procedures described previously[18].

to assume that neurones in the chicken retina which accumulated ^{3}H-GABA are probably GABAergic.

Examination of retinal sections processed sequentially for immunocytochemistry and autoradiography shows that the GABA-accumulating horizontal cells (Fig. 2*a*, *b*, open black arrows) in chicken retina do not contain enkephalins. Our double-label technique also reveals that some amacrine cells contain both enkephalins and GABA (Fig. 2, solid black arrows), whereas some GABA-accumulating amacrine cells (solid white arrows) do not contain enkephalins and some enkephalinergic neurones (open white arrows) appearently do not take up GABA.

The present study, together with our earlier finding[5], indicates that in both chicken and goldfish retinae, enkephalins inhibit the K$^+$-stimulated release of GABA from putative GABAergic amacrine cells. Furthermore, electrophysiological studies of the goldfish retina[5] suggest that opiate systems affect the information received by on-centre ganglion cells, by direct or indirect interactions involving enkephalinergic and GABAergic amacrine cells in the proximal region (sublamina b) of the inner plexiform layer. In most vertebrate retinae, sublamina b has been associated mainly with the processing of on-centre information, whereas the distal region (sublamina a) is involved with off-centre information[19–21]. If this aspect of retinal organization is conserved in the chicken retina, then our observation that enkephalinergic and GABAergic processes overlap in the proximal region of the inner plexiform layer (Fig. 2) suggests that as in the goldfish retina[5], interactions in the chicken retina may also influence the outflow of information to on-centre ganglion cells.

The finding that some GABA-accumulating amacrine cells in the chicken retina do not contain enkephalins is not surprising, as earlier studies have shown that although there was primarily one type of morphologically distinct enkephalin-immunoreactive amacrine cell[6,7,13–16], on the basis of somatic positions, there were several types of GABA-accumulating amacrine cells in the chicken retina[6,12]. Similarly, the co-localization of GABA and enkephalins in the same amacrine cells is consistent with recent reports that certain peptides and transmitters coexist in the same neurones[22–27]. In particular, enkephalin has been found in putative dopaminergic, serotoninergic and cholinergic neurones[23], and enkephalin-immunoreactive substances have been recently detected in putative GABAergic neurones from cultured embryonic chick cerebral hemisphere[24].

The functional significance for peptide–transmitter coexistence is unknown, although numerous possibilities have been suggested[23–28]. One such suggestion is that in the parasympathetic system innervating the urinary bladder, enkephalin, which is co-localized with acetylcholine[25], may function as an inhibitory transmitter by blocking the presynaptic release of acetylcholine[26]. Our finding that enkephalin inhibits GABA release from putative GABAergic amacrine cells is consistent with this hypothesis. However, our morphological findings suggest that enkephalin may also inhibit GABA release from putative GABAergic amacrine cells that do not contain enkephalin. Electron microscope studies involving the simultaneous visualization of ^{3}H-GABA uptake and enkephalin immunocytochemistry are consistent with both mechanisms. Our preliminary results indicate that while there are synaptic structures which label for both enkephalin immunoreactivity and ^{3}H-GABA uptake, there also exist enkephalinergic processes which form synaptic contacts on ^{3}H-GABA–accumulating profiles (C.B.W., unpublished observations). Thus, our results suggest that (1) at synapses where enkephalin and GABA are released from the same structure in response to depolarization, enkephalin might inhibit further GABA release at that synapse via a presynaptic mechanism and (2) at certain other synapses, enkephalin might diminish GABA release by interacting with opiate receptors located on neurones which contain GABA but not enkephalin. Probably, the most interesting conclusion from our data is that even within a single class of neurones such as the retinal amacrine cells, a neuroactive peptide and a neurotransmitter may coexist in some cells and be localized individually in different subpopulations.

We thank Ms Patricia Glazebrook and Mr Alex Kogan for technical assistance, Dr K.-J. Chang for anti-enkephalin antiserum and Ms Pat Cloud for typing the manuscript. Expression of Ti plasmid genes in monocotyledonous plants infected with *Agrobacterium tumefaciens*

G. M. S. Hooykaas-Van Slogteren, P. J. J. Hooykaas* & R. A. Schilperoort

MOLBAS Research Group, Department of Plant Molecular Biology,
Biochemical Laboratory, University of Leiden, Wassenaarseweg 64,
2333 AL Leiden, The Netherlands

When the bacterium *Agrobacterium tumefaciens* infects a fresh wound site on a dicotyledonous plant, it attaches to the plant cell wall and introduces a piece of its Ti plasmid DNA into the plant cell via an unknown mechanism[1–4]. This piece of Ti plasmid DNA (the T-DNA) becomes integrated in the nuclear genome of the plant cell and is transcribed into a specific number of different transcripts. The T-DNA renders the plant cell tumorous, and also codes for enzymes involved in the synthesis of certain tumour-specific compounds called opines. Any DNA segment inserted into the T-region of the Ti plasmid by genetic manipulation seems to be co-transferred to the plant cell by *A. tumefaciens*. Thus, the Ti plasmid offers great potential as a vector for the genetic engineering of plant cells. However, as monocots are not susceptible to tumour formation by *A. tumefaciens*, it is generally believed that the Ti plasmid can be used as a vector for dicotyledonous plants only[1–5]. This would severely limit the applicability of the Ti plasmid as a vector, as most commercially important crops are monocots. However, we report here data which indicate that the Ti plasmid may be a useful vector for transforming monocotyledonous plant species.

Infection of dicotyledonous plants with *A. tumefaciens* usually results in crown gall tumour formation, due to the expression of *onc* genes present in the T-DNA[6,7]. These *onc* genes enable crown gall cells to grow in the absence of the phytohormones auxin and cytokinin[6–8]. Recent evidence suggests that the *onc* genes in the T-DNA possibly code for enzymes that are directly involved in the biosynthesis of these hormones[9].

Tumorous plants can be derived from certain tobacco crown gall lines which spontaneously regenerate shoots. These shoots do not usually form roots, but they can develop into mature plants after grafting onto normal tobacco understems[10]. Superinfection of such plants with *A. tumefaciens* does not lead to tumour induction whereas infection with *A. rhizogenes*, which contains an Ri plasmid, results in the formation of an extensive swelling of the internodes having an infected wound rather than in the formation of a local tumour[10]. Similarly, infection of monocotyledonous plants with *A. tumefaciens* does not result in crown gall formation[11]. It is believed there is no T-DNA transfer to the tumour plant cells[12,13] or monocot cells[14], either because the bacterium cannot attach to the plant cell walls[12,14] or because of an abnormal phytohormone balance in such cells[14]. An alternative explanation is that T-DNA transfer did occur in these cases, but did not lead to tumour formation.

The opines octopine and nopaline are synthesized via enzymes that are encoded by T-DNA genes[15,16] which only have eukaryotic regulatory sequences for expression[17]. The detection of opines in plant cells is therefore direct evidence for the presence of T-DNA. To establish whether T-DNA is still transferred to and expressed in tumorous plants and monocots after infection with *A. tumefaciens*, we assayed for octopine and nopaline in plant material from infected wound sites via the method described by Otten and Schilperoort[18].

Grafted octopine tumour plants (from line TSO136)[19] were infected with *A. tumefaciens* strain LBA2318 (containing a nopaline Ti plasmid), strain LBA1020 (an Ri plasmid), and strain LBA2347 (carrying a nopaline Ti plasmid and an Ri plasmid). Infection with LBA2318 did not result in any swelling or tumour formation, but after infection with LBA1020 or LBA2347 small swellings were apparent (Fig. 1). Functions determined by the Ri plasmid thus stimulate the occurrence of swellings. Nopaline was detected in plant material isolated from the swellings

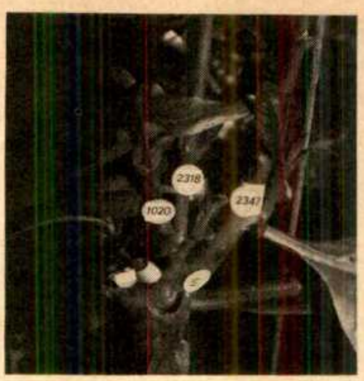

Fig. 1 Infection of a grafted crown gall shoot from line TSO136 with *A. tumefaciens* strains LBA1020, LBA2347 and LBA2318.

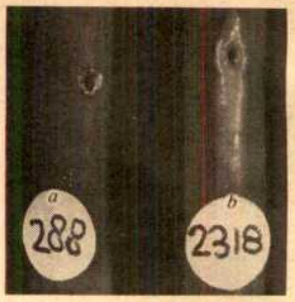

Fig. 2 Infection of *Narcissus* cv. 'Paperwhite' with avirulent *A. tumefaciens* strain LBA288 (*a*) and with virulent strain LBA2318 (*b*). Opine assays were performed as described elsewhere[18]. A small piece of tissue ($\sim 60\ \mathrm{mm}^3$) was extracted with 30 μl cold buffer, and the supernatant was mixed 1:1 with buffer and incubated for 60 min. At the start ($t=0$) and end ($t=60$) of the incubation period, 2-μl samples from the mix were spotted onto electrophoresis paper. After electrophoresis the paper was dried then stained with phenanthrene quinone reagent. Yellowish spots of guanidine compounds (such as arginine, octopine and nopaline) were visualized under long-wave UV. Tissues from both monocots and dicots (used as a control) infected with the nopaline strains LBA2318 or LBA2347 normally displayed a spot corresponding to nopaline at $t=0$ and $t=60$. In monocot or dicot tissues from plants infected with the octopine strains LBA1010 or LBA1023, a clear spot corresponding to octopine was visible only in the $t=60$ sample. This shows that in both infected dicot and monocot cells sufficient nopaline, but not enough octopine, accumulates for direct detection at $t=0$. Although octopine is not detected at $t=0$, octopine synthase activity is present which converts *in vitro* pyruvate and arginine into octopine so that at $t=60$ an octopine spot becomes visible. Neither octopine nor nopaline synthase activity was present in uninfected tissues from monocots or dicots, nor in tissues from plants infected with the avirulent strains LBA288 or LBA1516.

induced by LBA2347, which shows that the nopaline T-DNA from LBA2347 must have been introduced into the TSO136 crown gall cells. Therefore, we conclude that neither existing T-DNA, nor an altered phytohormone balance nor an altered cell wall are barriers to the transfer of T-DNA into the cells of the tumorous plant. The finding that introduction of a second copy of T-DNA into the tumorous shoots does not lead to tumour formation may be related to the abnormal phytohormone balance in the tumorous plants.

To determine whether monocots, which also do not show tumour formation after exposure to agrobacteria, can take up and express T-DNA after infection with *A. tumefaciens* we tested for production of opines in infected tissues. Two monocot species were selected for these studies, *Chlorophytum capense* (Liliaceae) and *Narcissus* cv. 'Paperwhite' (Amaryllidaceae). Plants of both species were infected with strain LBA2347. Fourteen days after infection small swellings were observed at the wound sites. After 21 days plant material from the wound sites always contained nopaline. In non-infected plant tissue neither octopine nor nopaline was detected. Following these positive results, infection tests were done on *Narcissus* cv. 'Paperwhite' with many different *A. tumefaciens* strains, LBA288 (Ti plasmid-cured; avirulent), LBA1516 (octopine Ti plasmid with a *vir*B mutation; avirulent), LBA1010 (octopine Ti plasmid), LBA2318 (nopaline Ti plasmid), LBA1023 (Ri plasmid plus octopine Ti plasmid), LBA2347 (Ri plasmid + nopaline Ti plasmid). After infection with the avirulent strains LBA288 and LBA1516 no swellings were formed, and in plant cells from wound sites infected with these strains, neither octopine nor nopaline was detected. After infection with any of the other strains small swellings were invariably formed (Fig. 2). In the case of the infection with LBA1010 or LBA1023, octopine was detected in the plant cells from the wound sites; in the case of infection with LBA2318 or LBA2347, nopaline was detected.

These results show for the first time both the occurrence of T-DNA transfer to cells of monocotyledonous plants, and the expression of the T-DNA genes for octopine and nopaline synthase in such cells. This latter finding suggests that the regulatory sequences which are essential for transcription and translation of the octopine and nopaline synthase genes in cells of dicots also function in monocots. This result is of great importance in the development of vectors with selectable markers for monocotyledonous plants.

Our results show that T-DNA transfer to monocots occurs from strains with a wild-type Ti plasmid, but not from strain LBA1516, which has a defect in one of its essential *vir* genes. Therefore it is likely that *A. tumefaciens* introduces T-DNA into cells of monocots and dicots via the same mechanism. Some years ago it was found that the attachment of *A. tumefaciens* to the plant cell wall is necessary for the bacterium to accomplish T-DNA transfer[20]. Our results suggest that *Agrobacterium* is able to attach to the cell walls of monocots. In support of this it has been shown recently that *A. tumefaciens* can attach to cells of *Asparagus officinalis* (a monocot)[21] which had not previously been found for other monocots[14]. The apparent discrepancy between these results might be explained by assuming that wounding can trigger transient changes in the cell walls of monocots which eventually enable *A. tumefaciens* to attach for a limited period of time.

T-DNA transfer to monocots is not accompanied by the induction of large crown gall tumours. The finding that the T-DNA genes for octopine and nopaline synthase are expressed in monocotyledonous plant cells suggests that the other T-DNA genes are also expressed in the monocot cells. Therefore the absence of proper tumour formation in monocots may be because monocot cells (like the octopine crown gall cells) do not respond to the products derived from the T-DNA encoded *onc* genes, perhaps because of peculiarities of their phytohormone metabolism.

We suggest that the Ti plasmid may emerge as a useful vector for monocotyledonous plants of the families Liliaceae and Amaryllidaceae. Further research is needed to establish whether crops from other monocot families (for example, Gramineae) can be transformed by the Ti plasmid. Nevertheless, our results have considerable implications for the biotechnology of a vast group of plant species of commercial interest.

We thank Drs A. Hoekema, L. Melchers and R. J. M. van Veen for critical reading of the manuscript.

Defending the Earth

Eric Ashby

International Environmental Policy: Emergence and Dimensions.
By Lynton K. Caldwell.
Duke University Press: 1984. Pp.367. Hbk $37.50, £28.50; pbk $14.75, £11.90.

ON 1 January 1970 the word "biosphere" was incorporated into the public laws of the United States of America. The word appears in the preamble to the Environmental Policy Act, 1969. It was one of many incidents — Britain's Wildlife and Countryside Act 1981 is another — in what some people call a "new environmental paradigm": a worldwide change in assumptions and beliefs about our responsibility for the rest of nature.

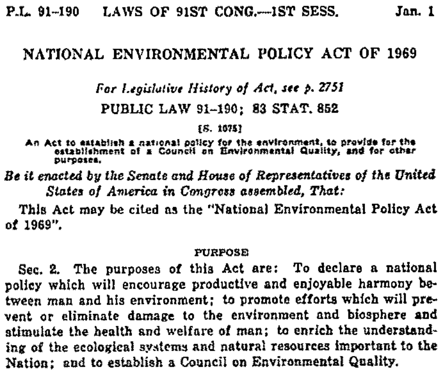
Are such incidents evidence of the emergence of a new paradigm? Lynton Caldwell believes that they are, and that is what this book is about. No one is better qualified then he to write such a book because he combines a capacity to digest huge masses of published material (the references in this book cover 56 pages of small print) with a capacity to write clearly and pungently. He has already described the gestation and birth of a national decision, the law to protect the environment of the United States (*Science and the National Environmental Policy Act*, reviewed in *Nature* **303**, 354; 1983). Now he takes a far wider view and offers a "sketch-description" of international decisions about environmental policy.

Caldwell himself would wish the book to be called only a sketch-description. He emphasizes that he writes at a high level of generalization and that a detailed analysis would require many volumes. It would be dull, too, and Caldwell's account is not. The book can be put in perspective by recalling something Caldwell wrote over a decade ago. Americans (and it is true for Europeans too) live in a "hypertrophic society":

> The hypertrophic society has fallen victim to a social 'disease', an 'endocrine failure' followed by runaway metabolism and accelerating growth. The negative feedback and homeostatic mechanisms that contain and project a stable self-renewing society have been supplanted by the self-generating impetus of positive feedback [*National Resources Journal;* Vol. 11, No. 3 (1971)].

Social carcinoma: a grim diagnosis. Caldwell's present theme is that a minority of thoughtful people all over the world are now aware of this "disease" and their influence is sufficient to persuade governments to take steps, even at an international level, to arrest its erosion of the biosphere. His book describes these international conferences, treaties, agreements, declarations; and he evaluates them with detachment.

The environmental movement, which (Caldwell thinks) recruits more people than join the world's peace movements, is an example that not only individuals but whole nations can learn from experience. People learn about something from press and television (the link between sulphur emissions and acid rain, for instance). It may then become an "issue". This in turn brings pressures upon governments to do something about the issue, at first at national level to satisfy self-interest and then, though much less effectively, internationally. That there has been any success at all at international level is remarkable when one considers how intense is the dislike, suspicion and jealously even between nations that are political allies. The only justification for hoping that international co-operation may become less difficult lies in the evidence summarized in Caldwell's book, fortified by a faith that the environmental movement is not a transient enthusiasm but "an awakening of modern man to a new awareness of the human predicament on earth".



P.L. 91-190 LAWS OF 91ST CONG.—1ST SESS. Jan. 1

NATIONAL ENVIRONMENTAL POLICY ACT OF 1969

For Legislative History of Act, see p. 2751

PUBLIC LAW 91-190; 83 STAT. 852

[S. 1075]

An Act to establish a national policy for the environment, to provide for the establishment of a Council on Environmental Quality, and for other purposes.

Be it enacted by the Senate and House of Representatives of the United States of America in Congress assembled, That:

This Act may be cited as the "National Environmental Policy Act of 1969".

PURPOSE

Sec. 2. The purposes of this Act are: To declare a national policy which will encourage productive and enjoyable harmony between man and his environment; to promote efforts which will prevent or eliminate damage to the environment and biosphere and stimulate the health and welfare of man; to enrich the understanding of the ecological systems and natural resources important to the Nation; and to establish a Council on Environmental Quality.

Law of change? The opening passages of the National Environmental Policy Act, which came into effect 15 years ago.

We have heard all this before, in the overwrought style of *Blueprint for Survival.* But the contrast between that sort of clamorous rhetoric and Caldwell's calm diagnosis is as wide as the contrast between a layman's guess and a medical consultant's considered opinion. Let me first say something about the facts in Caldwell's book and then offer an opinion about the faith needed to interpret the facts.

The prime fact was the United Nations Conference on the Human Environment, in Stockholm in 1972. The importance of this was not the meeting itself but the decades of activity preceding it; that is what made a conference inevitable. The conference itself was tedious and at times degenerated into political wrangling. But it had two important consequences: the first, to put environmental policies permanently on the agenda for national and international discussion; the second to create the United Nations Environment Programme (UNEP) which, although its achievements over the past ten years have been modest, has undoubtedly helped to bring environmental policies within the ambit of international law.

Since 1972 millions of man-hours have been spent and tons of print have been produced to promote international environmental policy. You can get an idea of the scale of effort from the list of bodies (all with acronyms conveniently listed in the book) concerned with the issues: there are over 200 of them. Some promising agreements have been reached at a regional level: the environmental directives that are complied with (more or less) by member states in the European Community are an example. And on paper, at any rate, there are numerous treaties, for instance to control endangered species, to conserve wetlands used by migrating birds, to stiffen protection against products harmful to health (a United Nations Resolution (37/137) adopted in 1981 with one dissentient: the United States!), to monitor long-range air pollution, to prevent pollution from ships, to conserve the Antarctic.

But does all this paperwork really mean that the paradigm is changing? Yes-and-no is the answer I gather from Caldwell's book. Yes, because this is just the kind of activity one expects before a paradigm-shift and it has no precedent. No, because international law and policing cannot alone cope with the issues; there will need to be a *massive* consensus which puts long-range interests before short-term convenience, and as yet there is no sign of that.

This is how Caldwell points to the problem.

> For as long as it pays people to destroy living systems unnecessarily, to deplete nonrenewable resources, and to degrade the quality of the biosphere, they may be expected to do so except as influenced by social or political constraints.

He has no patience with reports that are "long on 'musts' and 'shoulds' and very short on 'hows'". But he would surely agree that he is pretty short on "hows" himself, though he does encourage those who have seen the light to press on, regardless of setbacks, to learn by experience and to recruit supporters. A radical, lasting shift in attitudes may take a century; progress in any one lifetime may seem disheartening; but we have had an International Geophysical Year, a Global Atmospheric Research Programme, and in many nations already there is a public conscience about the environment which politicians and industrial corporations disregard at their peril.

It is to these signs of glacial change that Caldwell attaches his faith. But it is a sombre faith, laced with doubt. Here (on p. 274) is his conclusion:

> Barring unforeseen events, the ecological quality of the environment for all living things seems almost certain to suffer a net decline in the decades ahead....It is difficult to believe that a change in human perceptions and values could occur on a scale and within a period of time to reverse this pessimistic conclusion. Yet human history has recorded abrupt and unpredicted changes in social behavior. Events of the decade 1972–82 suggest that peoples and their governments are...developing an appreciation of the consequences of continuing along the path of ecologically heedless exploitation of the earth.

And if they do heedlessly continue? In the essay I quoted at the beginning of this review Caldwell gives his answer. The task, he wrote, is to cure the patient of the disease of societal hypertrophy. If:

> we are unable to avoid disaster, some moral satisfaction may be gained by the knowledge that our failure was not a failure of nerve or will...the outcome may be tragic; but it will be neither disgraceful nor absurd.

Here is encouragement to continue what Caldwell calls the "Defense of Earth". □

Place for biography in chemistry

Colin A. Russell

Amedeo Avogadro: A Scientific Biography.
By Mario Morselli.
Reidel: 1984. Pp. 375. Dfl. 160, £40.75, $59.50.
Boussingault: Chemist and Agriculturist.
By F.W.J. McCosh.
Reidel: 1984. Pp. 280. Dfl. 140, £35.50, $53.50.

CHEMICAL biography is not much in fashion today. There was a time when history of chemistry dominated history of science, but for some years the pendulum has swung far in other directions, especially towards the ubiquitous social history of scientific ideas and institutions. As for biography, many potential writers have been frozen into immobility by fears of perpetuating the cult of the scientific "hero" which, in these iconoclastic and egalitarian days, wouldn't do at all.

Yet biography is not hagiography and there still is a place for studies of our chemical forefathers. Indeed it is now necessary to replace the ageing monographs of a previous generation and to deploy the resources and display the insights of modern scholarship. Hence Reidel's conception of a series of books on "Chemists and Chemistry" is timely and welcome. The first two volumes are about the Italian aristocrat whose hypothesis was once familiar to every elementary student of chemistry, Amedeo Avogadro (1776–1856), and the French chemist J. B. J. D. Boussingault (1802–1887). If the order is alphabetical we shall have to wait some time for the volume on Zsigmondy.

In the first two books of any new series it would be hard to find a pair that differ more strikingly than these. At an editorial level alone they are far from homogeneous; one has American spelling and notes at the ends of chapters; the other uses English spelling and consigns notes to the back of the book. The systems of referencing are also entirely different, as are the use of page-headings and various other details. Perhaps only the fastidious will care for such things, but no one can fail to notice considerable differences of treatment. In part, no doubt, this springs from the subjects themselves. Boussingault, relatively unknown to all but a handful of historians, is chiefly memorable for his contributions (that *is* the right word) to agricultural science. Avogadro has a certain deathless reputation for enunciating the hypothesis connecting gas volumes and molecular numbers, so pointing a way out of the impasse over atomic weights that plagued chemistry for over half a century.

In his long-awaited volume, Morselli first traces the complicated political history of Piedmont where for centuries Avogadro's ancestors had lived. Though geographically part of Northern Italy it was, for most of Avogadro's life, part of the far-flung Kingdom of Sardinia, as well as being for some years a dependency of Napoleonic France. We read of his legal studies at Turin during which he was seduced into science, and of his appointment to chairs in physics and mathematics at, first, Vercelli, and then Turin itself. The scene being set we are next conducted, chapter by chapter, on a tour of Avogadro's scientific papers and their subsequent reception (or lack of it). As the subtitle indicates this is a *scientific* biography. After the first chapter little is heard of the political, social and cultural roots of the science described and there is no systematic attempt to relate them. This is consistent with the author's declared perception of dangers in "overly relating them [scientific theories] to earlier philosophical and cultural movements" (p. 356).

By contrast McCosh gives a more or less chronological account of Boussingault's life, from his childhood in war-torn Paris, through his unconventional scientific education at a mining school near Lyon to his adventures as teacher and scientific consultant in South America. He later became a collaborator of Dumas at the Sorbonne, professor at the Conservatoire des Arts et Métiers in Paris and pioneer in experimental farming in Alsace. He also worked in metallurgy, air and water analysis and on the thermal decomposition of barium peroxide. All this, and more, is described in detail and the social and scientific elements are woven into one tapestry. However, even this approach does not always show how Boussingault's science reflected social and other values and one is often left with more questions than answers. One welcome emphasis is on education, both given and received. The conclusion that Boussingault failed to become "a truly great chemist" because "he suffered from the lack of a university training" (p. 13) is, however, much too simple. It implies a systematic approach that was by no means always provided by universities, and neglects the many highly successful chemists who were denied any kind of undergraduate teaching.

Both Morselli and McCosh have written thorough, well-researched books. The adventures of Boussingault in South America are particularly well-told and should be of interest to many political historians who do not habitually read *Nature*. All who teach chemistry at school and have to conjure with the name of Avogadro will find Morselli's book an admirable corrective to popular errors. Such include the notion that Avogadro's solution to the atomic weight problem was immediately accepted by grateful colleagues, or (contrariwise) that he was totally ignored in his lifetime because he was a lawyer, inarticulate or Italian. Nor can the howlers be perpetuated that he proposed in 1811 diatomic molecules for the common elementary gases, or that he was instantly rescued from oblivion by Cannizzaro at the Karlsruhe Congress of 1860.

Of these two books Morselli's makes the more telling points because the scientific and historiographic issues have such unusual complexity and importance. But it has less relevant and fewer illustrations than its companion volume and a number of minor textual irritations. Thus Davy (whom McCosh usually calls "Humphrey") was not a single-minded supporter of contact electrification (Morselli, p. 63), nor was he a lifelong disciple of Boscovich (p. 199). Kekulé was certainly not a "close friend" of Frankland (p. 233), was not called "Frederick" and did not produce the first edition of his *Lehrbuch* in 1867 (p. 266). Prout's *Bridgewater Treatise* appeared in 1834 (p. 182), not 1904 (p. 184).

It is to be hoped that future volumes in the series will benefit from more careful editorial attention. In one chapter of Morselli, for example, an article by Graebe is given no less than five different abbreviated titles, while McCosh's book is marred by an extremely high number of misprints. Other than these blemishes the main deterrent is the price. But to those who can afford them both books have much to tell of the rise of modern chemistry. □

Colin Russell is Professor of History of Science and Technology at the Open University.

Pieces of artificial intelligence

Wendy G. Lehnert

Artificial Intelligence: Tools, Techniques, and Applications.
Edited by Tim O'Shea and Marc Eisenstadt.
Harper & Row: 1984. Pp.497. Pbk $19, £12.95,

TRUE to their title, O'Shea and Eisenstadt have produced an anthology of papers dealing with the tools, techniques and applications of artificial intelligence. However, while the book is intended to serve as an introduction to the field, it should not be seen as a textbook. The 15 chapters have been written by different authors and no effort has been made to achieve a unified effect, each contribution being a self-contained introduction to its own topic. As such, therefore, the book cannot be compared to single-author texts, for example Patrick Winston's *Artificial Intelligence* (published by Addison-Wesley in 1984), nor does it attempt to provide the comprehensive coverage of the three volumes of *The Handbook of Artificial Intelligence* by A. Barr, P. Cohen and E.A. Feigenbaum (Pitman, 1981 and 1982). But viewed as a *collection* of introductory papers, it is reasonably solid.

Here students of AI will find well-presented material that is certain to motivate further delving into the literature. Among the topics covered are natural language, vision, robotics and expert systems, as well as introductions to the LISP and PROLOG programming languages. There is, too, an account of text processing, which really has nothing to do with AI but does show how AI techniques can be useful in spin-off applications.

There is also a chapter on how to get a PhD in AI, apparently aimed at graduate students who have no adviser. As a teacher, I found this contribution laudable in intent but irresponsible in practice. It gives the impression that a PhD in AI can be pursued by anyone with sufficient interest in the subject and access to adequate computing facilities. In fact, there are only a few computer science departments capable of supporting quality research in AI, and all such research is conducted in the context of organized projects. Since there is a very high demand for well-qualified people in AI, and a paucity of such people to go around, there is a grave danger that third-rate research will be accepted at lesser institutions for the sake of exploiting the bullish job market. A trend in this direction could hurt AI irreparably by destroying what delicate credibility has been established by more responsible research sites: a field that is as controversial and susceptible to media hype as AI cannot afford to make room for mediocre practitioners. So I fail to see how this chapter will help anyone, and I fear it will only serve to encourage borderline research.

That chapter apart, my reaction to the collection is largely positive. The various contributions grew out of a school which was aimed at both academic and industrial participants, so the book should be read in the same spirit with which one approaches a conference proceedings volume. The quality varies from paper to paper and readers are left to discover for themselves any unifying threads between topics. But given additional guidance to make more explicit the underlying principles of AI, the book does provide a good introductory background to the field. I would therefore suggest that teachers use it as a supplementary text, or as a source of selected readings, and it should certainly be included in any library intending to keep a comprehensive collection of the AI literature. □

Spasm? Or rigor?

Michael Spencer

Contractile Mechanisms in Muscle.
Edited by G.H. Pollack and H. Sugi.
Plenum: 1984. Pp. 921. $125, £106.25.

IN THE heady years of the 1960s, D.R Wilkie advertised a lecture on muscle with a jokey prospectus that started: "Available *now*. LINEAR MOTOR. Rugged and dependable: design optimized by world-wide field testing over an extended period" and ended with the laconic phrase "Good to eat". Optimism was in the air. Nobody knew exactly what made the filaments slide, but there was no shortage of ingenious hypotheses. As few of these could immediately be tested, imaginations roamed freely; among ideas discussed were crossbridges on springs, erectile crossbridges, contractile filaments and various wheezes involving forces at a distance.

As the 1970s dawned, the rocking crossbridge model emerged as front-runner with influential backing from the two Huxleys and others. It looked ideally suited to the simple four-stage kinetic scheme of Lymn and Taylor, with a powered change in the angle of attachment corresponding to one of the steps. It seemed inevitable that time-resolved studies by X-ray and other techniques would soon sort it all out, and Nobel-spotters made mental bets on the likely beneficiaries.

Then troubles began to mount, and nagging doubts to arise. X-ray work of ever-increasing sophistication and cost failed to reveal any obvious correlation with kinetics; and the kinetic schemes themselves became so complex that E.W Taylor once started a lecture by observing drily that we now knew less than we did two years earlier. Worst of all, a series of new experiments with fluorescent and EPR probes failed to provide any consistent evidence that the crossbridges rocked at all. Heretics who had temporarily been silenced began to raise their voices: was the supposed mainstream of muscle research really a blind channel? At the present time few workers are sure of anything any more, and there is a desperate feeling that although no alternative scheme is highly plausible, there is some vital feature missing from the crossbridge hypothesis.

Young post-doctorals just entering the field are less afflicted by self-doubt than their more world-weary elders, and for them there is no shortage of work: many types of muscle remain almost virgin territory, and there are fascinating new techniques to spend money on. So the flow of bulky conference reports continues unabated, and the volume under review is typical: it records the second international symposium on crossbridge mechanisms and contains around half-a-million words, ending with a ruminative summary (expressing due gratitude to the organizers) by one of the grand masters of the field. The fact that the conference took place more than two years ago is, however, significant: the reprehensible delay in publication has not in fact rendered most of the material obsolete, because progress just isn't that fast any more.

The main topics covered by the meeting were structural dynamics, including the curious affair of the shortening thick filaments in *Limulus*; mechanics, particularly tension transients and stiffness; and energetics. The text is enlivened by reports of verbal exchanges, such as this baffling dialogue:

A: Where you say A-band mass, you don't actually mean "mass" do you?
B: What would you have me say?
A: Whatever you mean — what *do* you mean?

or this outburst from an exasperated critic:

X: I mean you've just done the control, got the wrong results, and then persist in fitting your hypothesis?
Y: No . . .

A lot of effort at the conference went into reconciling the evidence from spectroscopic probes with the rocking crossbridge model: if the probes showed no motion, could they all have been attached (by sheer bad luck) to a portion of the myosin head that remained fixed to actin, while another unlabelled portion did the rocking? The need for detailed crystallographic structures of the relevant proteins was heavily emphasized; and there is now (two years later) a glimmer of hope that this may be achieved before the retirement dates of those who have devoted their lives to the crossbridge hypothesis.

It would be a mistake to belittle this obsession with molecular detail by comparing it with the fruitless debates of mediaeval theologians, as Graham Hoyle tends to do in his recent book (*Muscles and their Neural Control*, published by Wiley in 1983). If (dreadful thought) the crossbridge head turns out not to be the source of motion after all, then belated and more widespread attention will have to be given to iconoclastic ideas such as W.F. Harrington's contractile S-2 region, or to charge-effect hypotheses of the kind adhered to by G.F. Elliott. Neither of the last-named workers presented papers at the conference in question, but occasional references to their thoughts appear in the proceedings like Banquo's ghost at the feast in *Macbeth*.

It is imperative to resolve the uncertainties — not just for the satisfaction of those involved with muscle, but because motility is now seen to be of such universal importance in cell biology. The muscle proteins or their analogues are so widely distributed among cell types that a single basic mechanism seems rather likely, even though control systems vary considerably. It remains a central problem to find out exactly what goes on, and the present uncomfortable state of spasm in the field must surely soon be succeeded by purposeful movement. □

Michael Spencer has just given up being a Senior Research Fellow in the Department of Biophysics at King's College, University of London.

Starting with laser spectroscopy

G.R. Wilkinson

Foundations of Laser Spectroscopy.
By Stig Stenholm.
Wiley: 1984. Pp. 268. £40.95, $36.95.

ALTHOUGH the laser was invented before most of our undergraduates and postgraduates were born, laser spectroscopy is still a young and active area of research. Hence Dr Stenholm's book, which expounds upon the foundations of the subject, is likely to be widely read.

The author starts by establishing a notation and recalls the basic principles of electrodynamics and quantum mechanics. Following this introductory material is a chapter in which the response of the laser medium to strong electromagnetic fields is derived, and another which treats the physical basis of laser operation (this latter account might have been more useful if consideration of the working of some actual lasers had been included). The next chapter contains description of some applications to laser spectroscopy; here I found the treatment rather abstract for the average reader, who will have to look elsewhere for a review of the spectroscopy involved in lasers. Fluctuations are concisely introduced in Chapter 5, whilst finally field quantization and some of the simplest consequences are discussed. The book contains helpful comment and references at the end of each chapter.

The author, a theoretical physicist,

> intends this volume for beginning theorists and experimentalists who lack extensive training in algebraic manipulations, hence it contains more equations than are needed for readers more accustomed to mathematical sophistication.

This is indeed one of the book's most valuable features; however I am not sure that the claim that it can be used as a textbook for a course, even without previous knowledge of laser physics, is valid. For example it is disappointing to find that the author has left out mention of processes belonging to non-linear optics as these are so prominent at the present time.

Despite the misgivings that I have as a spectroscopist, this is undoubtedly an important book, and one which will not date quickly. Every worker in the field of laser spectroscopy should have access to a copy. □

G. R. Wilkinson is Professor of Physics at King's College, University of London.

BOOKS RECEIVED

Technology

Advances in Cryogenic Engineering, Vol. 29. R.W. FAST (ed.). *Plenum: 1984. Pp. 1049. ISBN 0-306-41703-0. Np.*

Advances in Energy Systems and Technology, Vol. 4. PETER AUER and DAVID DOUGLAS (eds). *Academic: 1983. Pp. 213. ISBN 0-12-014904-4. $49.*

First European Conference on Coal Liquid Mixtures. INSTITUTION OF CHEMICAL ENGINEERS. *Pergamon: 1983. Pp. 415. ISBN 0-08-031397-3. £27, $48.50.*

Heterogeneous Reactions: Analysis, Examples, and Reactor Design. Vol. 2 Fluid–Fluid–Solid Reactions. By L.K. DORAISWAMY and M.M. SHARMA. *Wiley: 1984. Pp. 374. ISBN 0-471-05367-8. £59.35.*

Ion Exchange Technology. D. NADEN and M. STREAT (eds). *Ellis Horwood: 1984. Pp. 742. ISBN 0-85312-770-0. £45.00.*

Rainfall as the Basis for Urban Run-off Design and Analysis. Water Science & Technology, Vol. 16, Nos 8-9. PETER HARREMOES (ed.). *Pergamon: 1984. Pp. 368. ISBN 0-08-031506-2. £50.00.*

River Basin Management. Water Science & Technology, Vol. 16, Nos 5-7. D.H. NEWSOME and A.M.C. EDWARDS (eds). *Pergamon: 1984. Pp. 670. ISBN 0-08-031505-4. £75.00.*

Robots and Telechairs: Manipulators with Memory; Remote Manipulators; Machine Limbs for the Handicapped. By M.W. THRING. *Ellis Horwood: 1983. Pp. 298. ISBN 0-85312-274-1. £27.50.*

THRING. *Ellis Horwood: 1983. Pp. 298. ISBN 0-85312-274-1. £27.50.*

The Silicon Idol: The Micro Revolution and its Social Implications. By MICHAEL SHALLIS. *Oxford University Press: 1984. Pp. 188. ISBN 0-19-215877-5. £8.95.*

Stepping Motors and their Microprocessor Controls. By TAKASHI KENJO. *Oxford University Press: 1984. Pp. 244. ISBN 0-19-859326-0. £25.*

Treatise on Materials Science and Technology. Vol. 19 Experimental Methods Part B. HERBERT HERMAN (ed.). *Academic: 1983. Pp. 274. ISBN 0-12-341842-9. $45.*

Computer Science

The Computer Comes of Age: The People, the Hardware, and the Software. By R. MOREAU. *MIT Press: 1984. Pp. 227. ISBN 0-262-13194-3. £17.95.*

Computing in Applied Science. By WILLIAM J. THOMPSON. *Wiley: 1984. Pp. 325. ISBN 0-471-09355-6. £26.70.*

The Electronic Library. By KENNETH E. DOWLIN. *Mansell Publishing: 1984. Pp. 199. Pbk ISBN 0-918212-75-8. Pbk £21.*

The Robot Revolution. By TOM LOGSDON. *Simon & Schuster: 1984. Pp. 207. Pbk ISBN 0-671-46705-0. Pbk $9.95.*

SPSS/PRO For Dec Professional 350. *McGraw-Hill: 1984. Pp. 282. ISBN 0-07-046556-8. Np.*

Super-Computers and Parallel Computation. D.J. PADDON (ed.). *Oxford University Press: 1984. Pp. 258. ISBN 0-19-853601-1. £25.*

Text Processing. Cambridge Computer Science Texts 20. By A. COLIN DAY. *Cambridge University Press: 1984. Pp. 141. Hbk ISBN 0-521-24432-3; pbk ISBN 0-521-28683-2. £14, $29.95; pbk £5.95, $12.95.*

Biological Sciences

Advances in Lipid Research, Vol.20. RODOLFO PAOLETTI and DAVID KRITCHEVSKY (eds). *Academic: 1983. Pp.367. ISBN 0-12-024920-0. $48.50.*

Advances in Metabolic Disorders, Vol.10, CNS Regulation of Carbohydrate Metabolism. ANDREW J. SZABO (ed.). *Academic: 1983. Pp. 508. ISBN 0-12-027310-1. $65.00.*

Advances in Virus Research, Vol. 28. MAX A. LAUFFER and KARL MARAMOROSCH (eds). *Academic: 1983. Pp.478. ISBN 0-12-039828-1. $59.*

The Alkaloids: Chemistry and Pharmacology, Vol.22. ARNOLD BROSSI (ed.). *Academic: 1983. Pp.342. ISBN 0-12-469522-1. $50.00.*

Amino Acids: Biosynthesis and Genetic Regulation. KLAUS M. HERRMANN and RONALD L. SOMERVILLE (eds). *Addison-Wesley: 1983. Pp.453. ISBN 0-201-10520-9. $41.95.*

Anatomy and Physiology, 2nd Edn. By EDWIN B. STEEN and ASHLEY MONTAGU. *Harper & Row: 1984. Pp.406. Pbk ISBN 0-06-460190-0. Pbk £4.95.*

Ants. By PAT and HELEN CLAY. *Adam & Charles Black: 1984. Pp.25. ISBN 0-7136-2386-1. £3.50.*

The Bacterial Cell Surface. By STEPHEN M. HAMMOND, PETER A. LAMBERT and ANDREW N. RYCROFT. *Croom Helm: 1984. Pp.226. Hbk ISBN 0-7099-1229-3; pbk ISBN 0-7099-1267-6. Hbk £22.50; pbk £10.95.*

Badgers. By ERNEST NEAL. *Adam & Charles Black: 1984. Pp.25. ISBN 0-7136-2389-6. £3.50.*

Basic Marine Biology. By A.A. FINCHAM. *Cambridge University Press: 1984. Pp.157. Hbk ISBN 0-521-26421-9; pbk ISBN 0-521-26966-0. Hbk £20, $36; pbk £7.95, $14.95.*

Biological Foundations and Human Nature. The Katzir–Katchalsky Lecture Series. MIRIAM BALABAN (ed.). *Academic: 1983. Pp.243. ISBN 0-12-076150-8. $39.50, £28.*

Biological Macromolecules and Assemblies. Vol. 1: Virus Structures. FRANCES A. JURNAK and ALEXANDER MCPHERSON (eds). *Wiley: 1984. Pp.397. ISBN 0-471-87077-3. £69.25.*

Biological Oceanographic Processes, 3rd Edn. By TIMOTHY R. PARSONS, MASAYUKI TAKAHASHI and BARRY HARGRAVE. *Pergamon: 1984. Pp.330. ISBN 0-08-030765-5. £10.95, $19.75.*

Biology of Chrysopidae. M. CANARD, Y. SEMERIA and T.R. NEW (eds). *Dr W. Junk: 1984. Pp.288. ISBN 90-6193-137-1. Dfl. 150, £38.*

The Biology of Crustacea, Vol. 7. E. JOHN VERNBERG and WINONA B. VERNBERG (eds). *Academic: 1983. Pp.338. ISBN 0-12-106407-7. $45.00.*

Biology of Microorganisms, 4th Edn. By THOMAS D. BROCK, DAVID W. SMITH and MICHAEL T. MADIGAN. *Prentice/Hall: 1984. Pp.847. Pbk ISBN 0-13-078338-2. Pbk £14.95.*

Black Caribs: A Case Study in Biocultural Adaptation. Current Developments in Anthropological Genetics, Vol.3. MICHAEL H. CRAWFORD (ed.). *Plenum: 1984. Pp.395. ISBN 0-306-41308-6. £59.50.*

Cardiovascular Review 1984. By GERALD C. TIMMIS *et al. Academic: 1984. Pp.705. ISBN 0-12-691346-3. $44.*

Cellular Ageing. Monographs in Developmental Biology 17. H.W. SAUER (ed.). *Karger: 1984. Pp.278. ISBN 3-8055-3860-X. SwFr. 148, DM 177, $88.75.*

CMV: Pathogenesis and Prevention of Human Infection. STANDLEY A. PLOTKIN, SUSAN MICHELSON, JOSEPH S. PAGANO and FRED RAPP (eds). *Alan R. Liss: 1984. Pp.515. ISBN 0-8451-1057-8. £67.00.*

Coastal Waders and Wildfowl in Winter. P.R. EVANS, J.D. GOSS-CUSTARD and W.G. HALE (eds). *Cambridge University Press: 1984. Pp.331. ISBN 0-521-25928-2. £27.50, $54.50.*

Competition Models in Population Biology. By PAUL WALTMAN. *Wiley: 1984. Pp.77. Pbk ISBN 0-89871-188-6. Pbk £8.*

Comprehensive Endocrinology. The Pineal Gland. RUSSEL J. REITER (ed.). *Raven: 1984. Pp.394. ISBN 0-89004-314-0. $68.50.*

Current Topics in Eye Research Vol. 4. JOSE A. ZADUNAISKY and HUGH DAVSON (eds). *Academic: 1984. Pp.227. ISBN 0-12-153004-3. $73.00, £56.50.*

Current Topics in Membranes and Transport, Vol. 22: The Squid Axon. PETER F. BAKER (ed). *Academic: 1984. Pp.593. ISBN 0-12-153322-0. $89, £62.50.*

Cytology of the Central Nervous System. By DOROTHY L. ROSENTHAL. *Karger: 1984. Pp.206. ISBN 3-8055-3808-1. SwFr. 98, DM 117, $58.75.*

Development of Nerve Cells and their Connections. By W.G. HOPKINS and M.C. BROWN. *Cambridge University Press: 1984. Pp.137. ISBN 0-521-25344-6; pbk ISBN 0-521-27725-0. Hbk £16, $29.95; pbk £6.95, $13.95.*

Developmental Biology of Cultured Nerve, Muscle, and Glia. By DAVID SCHUBERT. *Wiley: 1984. Pp.315. ISBN 0-471-86592-3. £49.45.*

Disease Resistance in Plants, 2nd Edn. By J. E. VANDERPLANK. *Academic: 1984. Pp.194. ISBN 0-12-711442-4. $34.50, £24.50.*

Ecology and Evolutionary Biology: A Round Table on Research. GEORGE W. SALT (ed.). *University of Chicago Press: 1984. Pp.130. Pbk ISBN 0-226-73443-9. Pbk £6.75.*

The Ecology of Neotropical Savannas. By GUILLERMO SARMIENTO. Translated by OTTO SOLBRIG. *Harvard University Press. 1984. Pp.235. ISBN 0-674-22460-4. £19.10.*

Ecology of Saprotrophic Fungi. By R.C. COOKE and A.D.M. RAYNER. *Longman: 1984. Pp.415. ISBN 0-582-44262-1. £20.*

Ecosystem Homeostasis. By PREZEMYSŁAW TROJAN. *Dr. W. Junk: 1984. Pp.132. Pbk ISBN 90-6193-622-5. Pbk Dfl. 85, $32, £21.50*

The Endocrinology of Pregnancy and Parturition. Current Topics in Experimental Endocrinology, Vol 4. L. MARTINI and V.H.T. JAMES (eds). *Academic: 1983. Pp.290. ISBN 0-12-153204-6. $44.50.*

The Enzymes, 3rd Edn. Vol.16. Lipid Enzymology. PAUL D. BOYER (ed.). *Academic: 1983. Pp.783. ISBN 0-12-122716-2. $79.00.*

Essential Reproduction, 2nd Edn. By MARTIN JOHNSON and BARRY EVERITT. *Blackwell. 1984. Pp.367. ISBN 0-632-01258-7. £10.80.*

Evolution of Domesticated Animals. I. L. MASON (ed.). *Longman: 1984. Pp.452. ISBN 0-382-46046-8. £35.*

Evolutionary Ecology. B. SHORROCKS (ed.). *Blackwell Scientific: 1984. Pp.418. ISBN 0-632-01189-0. £25.80.*

Evolutionary Theory: Paths into the Future. J.W. POLLARD (ed.). *Wiley: 1984. Pp 271. ISBN 0-471-90026-5. £21.50.*

Fetal Endocrinology and Metabolism. Current Topics in Experimental Endocrinology, Vol. 5. L. MARTINI and V.H.T. JAMES (eds) *Academic: 1983. Pp.363. ISBN 0-12-153205-4. $48.00.*

Fish Physiology, Vol.9. W.S. HOAR, D.J. RANDALL and E.M. DONALDSON (eds). *Academic: 1983. Pp.477. ISBN 0-12-350429-5. $52.00.*

Fish Physiology, Vol.9, Part A. W.S. HOAR, D.J. RANDALL and E.M. DONALDSON (eds). *Academic: 1983. Pp.483. ISBN 0-12-350409-0. $59.00.*

Free Radicals in Biology, Vol. VI. WILLIAM A. PRYOR (ed.). *Academic: 1984. Pp 437. ISBN 0-12-566506-7. $75, £52.50.*

From Neuron to Brain, 2nd Edn. By STEPHEN W. KUFFLER, JOHN G. NICHOLLS and A. ROBERT MARTIN. *Sinauer: 1984. Pp.651. ISBN 0-87893-443-X. Np.*

Frontiers of Oral Physiology. Steroid Hormones in Saliva. D.B. FERGUSON (ed.). *Karger: 1984. Pp.162. ISBN 3-8055-3848-0. SwFr. 115, DM 138, $69.*

A Functional Biology of Free-Living Protozoa. By JOHANNA LAYBOURN-PARRY. *Croom Helm: 1984. Pp.218. Hbk ISBN 0-7099-1625-6; pbk ISBN 0-7099-1678-7. Hbk £16.95; pbk £8.95.*

Ganglioside Structure, Function, and Biomedical Potential. Advances in Experimental Medicine and Biology, Vol. 174. ROBERT W. LEDEEN, ROBERT K. YU, MAURICE M. RAPPORT and KUNIHIKO SUZUKI (eds). *Plenum: 1984. Pp.649. ISBN 0-306-41707-3. Np.*

Gastrointestinal Disorders of the Elderly. By LAWRENCE J. BRANDT. *Raven Press: 1984. Pp. 636. ISBN 0-89004-987-4. $80.50.*

Genetic Analysis of the Cell Surface. Receptors and Recognition, Series B, Vol. 16. P. GOODFELLOW (ed.). *Chapman & Hall: 1984. Pp.193. ISBN 0-412-25070-5. £27.50.*

Genetics and Development. By JAMES H. SANG. *Longman: 1984. Pp.398. Pbk ISBN 0-582-44681-3. Pbk £13.95.*

Growth and Maturation Factors, Vol. 2. GORDON GUROFF (ed.). *Wiley: 1984. Pp.340. ISBN 0-471-09708-X. £66.*

Handbook of the Birds of India and Pakistan, 2nd Edn. Vol. 4, Frogmouths to Pittas. By SALIM ALI and S. DILLON RIPLEY. *Oxford University Press: 1984. Pp.267. ISBN 0-19-561551-4. £19.50.*

Hydrobiology of the Mangal. Developments in Hydrobiology. FRANCIS DOV POR and INKA DOR (eds). *Dr W. Junk: 1984. Pp.264. ISBN 90-6193-771-X. Dfl. 180, £45.75.*

BOOKS RECEIVED

Immunologische Abwehr and Krebs. By JÜRGEN MILLECK. *Akademie-Verlag, Berlin: 1984. Pp.139. DM 48.*

Immunology of Anergy and Systemic Lupus Erythematosus. Progress in Allergy, Vol. 35. R.S. SCHWARTZ (ed.). *Karger: 1984. Pp.176. ISBN 3-8055-3824-3. DM 117, $58.75.*

In a Patch of Fireweed: A Biologist's Life in the Field. By BERND HEINRICH. *Havard University Press: 1984. Pp.194. ISBN 0-674-44548-1. £15.70.*

Infanticide: Comparative and Evolutionary Perspectives. GLENN HAUSFATER and SARAH BLAFFER HARDY (eds). *Walter de Gruyter: 1984. Pp.598. ISBN 0-202-02022-3. $34.95.*

International Review of Cytology, Vol. 81. G.H. BOURNE and J.F. DANIELLI (eds). *Academic: 1984. Pp.295. ISBN 0-12-364481-X. $39.50.*

International Review of Cytology, Vol. 89. G.H. BOURNE and J.F. DANIELLI (eds). *Academic: 1984. Pp.359. ISBN 0-12-364489-5. $49.50, £35.00.*

Intrahepatic Calculi. Progress in Clinical and Biological Research, Vol. 152. KUNIO OKUDA, FUMIO NAKAYAMA and JOHN WONG (eds). *Alan R. Liss: 1984. Pp.352. ISBN 0-8451-5002-2. £60.00.*

Introduction to Molecular Immunology, 2nd Edn. By ALFRED NISONOFF. *Sinauer: 1984. Pp.236. ISBN 0-87893-595-9. £12.80.*

Invertebrate–Microbial Interactions. Joint Symposium of The British Mycological Society and the British Ecological Society held at the University of Exeter, September 1982. J.M. ANDERSON *et al.* (ed.). *Cambridge University Press: 1984. Pp. 349. ISBN 0-521-25395-0. £40.00, $79.50.*

Lecture Notes on Coastal and Estuarine Studies. Vol. 6, Ecology of Barnegat Bay, New Jersey. MICHAEL J. KENNISH and RICHARD A. LUTZ (eds). *Springer-Verlag: 1984. Pp. 396. Pbk ISBN 3-540-90935-4/0-387-90935-4. Pbk DM 96, $37.70.*

The Leukotrienes: Chemistry and Biology. LAWRENCE W. CHAKRIN and DENIS M. BAILEY (eds). *Academic: 1984. Pp.308. ISBN 0-12-166750-2. $52.*

Federal Biotechnology Funding Sources

Oskar R. Zaborsky, Ph.D.
Brenda K. Young

Vital information on U.S. government programs for:

- Research Scientists and Engineers
- R&D Administrators
- High-Tech Small Businessmen

This invaluable 262-page guide provides the most up-to-date information on extramural R&D programs.

It identifies and describes:

- 329 programs; within
- 33 federal departments and agencies; and
- 282 key contact individuals.

Federal Biotechnology Funding Sources
ISBN 0-931283-23-X
$69.95

Circle No. 46 on Reader Service Card.

Metabolism of Hormonal Steroids in the Neuroendocrine Structures. Serono Symposia Publications Vol. 13. F. CELOTTI, F. NAFTOLIN and L. MARTINI (eds). *Raven: 1984. Pp. 213. ISBN 0-89004-510-0. $49.*

Methods in Enzymology. Vol. 96 Biomembranes. SIDNEY FLEISCHER and BECCA FLEISCHER (eds). *Academic: 1984. Pp. 901. ISBN 0-12-181996-5. $79.*

Methods in Enzymology, Vol. 102. Hormone Action Part G, Calmodulin and Calcium-Binding Proteins. ANTHONY R. MEANS and BERT W. O'MALLEY (eds). *Academic: 1983. Pp. 336. ISBN 0-12-182002-5. $41.50.*

Methods for the Study of Marine Benthos, 2nd Edn. N.A. HOLME and A.D. McINTYRE (eds). *Blackwell: 1984. Pp. 387. ISBN 0-632-00894-6. £25.00.*

Mice. By RON WILSON. *Adam & Charles Black: 1984. Pp. 25. ISBN 0-7136-2388-8. £3.50.*

Molecular and Cellular Basis of Visual Acuity. S. ROBERT HILFER and JOEL B. SHEFFIELD (eds). *Springer-Verlag: 1984. Pp. 184. ISBN 3-540-90964-8/0-540-90964-8. DM 98, $38.50.*

Molecules and Evolution. By A. CULLINAN. *British Museum (Natural History): 1984. Pp. 17. Pbk ISBN 0-565-00858-7. Pbk £1.50.*

The Mollusca. Vol. 6 Ecology. W.D. RUSSEL-HUNTER (ed.). *Academic: 1983. Pp. 695. ISBN 0-12-751406-6. $69.*

Monoclonal Antibodies and Functional Cell Lines. ROGER H. KENNETT, KATHLEEN B. BECHTOL and THOMAS J. McKEARN (eds). *Plenum: 1984. Pp. 426. ISBN 0-306-41567-4. Np.*

Muscle and Nonmuscle Motility. Vol. 1. ALFRED STRACHER (ed.). *Academic: 1983. Pp. 372. ISBN 0-12-673001-6. $45.*

Muscle and Nonmuscle Motility, Vol. 2. ALFRED STRACHER (ed.). *Academic: 1983. Pp. 211. ISBN 0-12-673002-4. $34.50.*

Mutations in Man. GÜNTER OBE (ed.). *Springer-Verlag: 1984. Pp.327. ISBN 3-540-13113-2/0-387-13113-2. DM 116, $45.50.*

Myelofibrosis and the Biology of Connective Tissue. Progress in Clinical and Biological Research, Vol. 154. PAUL D. BERK, HUGO CASTRO-MALASPINA and LOUIS R. WASSERMAN (eds). *Alan R. Liss: 1984. Pp. 520. ISBN 0-8451-50004-9. £52.00.*

Neurobiology of the Trace Amines. Analytical, Physiological, Pharmacological, Behavioural and Clinical Aspects. ALAN A. BOULTON *et al.* (eds). *Humana Press: 1984. Pp. 624. ISBN 0-89603-063-6. $59.50.*

Neurocommunications: An Introduction. By I.C. WHITFIELD. *Wiley: 1984. Pp. 304. ISBN 0-471-10320-9. £17.*

Neuroendocrine Aspects of Reproduction. REID L. NORMAN (ed.). *Academic: 1984. Pp. 430. ISBN 0-12-521480-4. $46.*

Neuroendocrinology and Psychiatric Disorder. GREGORY M. BROWN, STEPHEN H. KOSLOW and SEYMOUR REICHLIN (eds). *Raven: 1984. Pp. 448. ISBN 0-89004-742-1. $73.50.*

Neuroimmunology. Serono Symposia Publications Vol. 13. PETER O. BEHAN and FEDERICO SPREAFICO (eds). *Raven: 1984. Pp. 500. ISBN 0-89004-963-7. $105.50.*

New Manual of Bryology. Vol. 1. RUDOLF M. SCHUSTER (ed.). *Hattori Botanical Laboratory, Miyazaki-ken 889-25, Japan: 1984. Pp. 626. ISBN 4-938163-3045. Np.*

General

Collins Guide to the Grasses, Sedges, Rushes and Ferns of Britain and Northern Europe. By RICHARD FITTER and ALASTAIR FITTER. *Collins: 1984. Pp.256. Pbk ISBN 0-00-219136-9. Pbk £5.95.*

Continuities and Discontinuities in Development. ROBERT N. EMDE and ROBERT J. HARMON (eds). *Plenum: 1984. Pp.418. ISBN 0-306-41563-1. Np.*

The Dynamics of Nuclear Proliferation. By STEPHEN M. MEYER. *University of Chicago Press: 1984. Pp.229. ISBN 0-226-52148-6. £17.*

Economic Perspectives on Acid Deposition Control. Acid Precipitation Series Vol.8. THOMAS D. CROCKER (ed.). *Butterworth: 1984. Pp.180. ISBN 0-250-40573-3. Np.*

European Mires. PETER MOORE (ed.). *Academic: 1983. Pp.384. ISBN 0-12-505580-3. £49; $75.*

Evaluation of Research and Development. Proceedings of the Seminar held in Brussels, Belgium, October 17–18, 1983. G. BOGGIO and E. SPACHIS-PAPAZOIS (eds). *Reidel: 1984. Pp.147. ISBN 90-277-1759-1. $27.*

The Food Scandal. By CAROLINE WALKER and GEOFFREY CANNON. *Century: 1984. Pp.190. ISBN 0-7126-0906-7. £7.50.*

A Generous Confidence. Thomas Story Kirkbride and the Art of Asylum-Keeping, 1840–1883. By NANCY TOMES. *Cambridge University Press: 1984. Pp.387. ISBN 0-521-24172-3. £27.50, $39.50.*

Health Information Systems: A Bibliography. By DONALD G. ZIEGENFUSS and JAMES T. ZIEGENFUSS. *Plenum: 1984. Pp.247. ISBN 0-306-65208-0. $85.*

Human Laterality. By MICHAEL C. CORBALLIS. *Academic: 1984. Pp.255. ISBN 0-12-188180-6. $29.*

Introduction to Wastewater Treatment Processes, 2nd Edn. By R.S. RAMALHO. *Academic: 1984. Pp.580. ISBN 0-12-576560-6. $57.*

John Muir Summering in the Sierra. ROBERT ENGBERG (ed.). *University of Wisconsin Press: 1984. Pp.160. Pbk ISBN 0-299-09624-6. Hbk £20.40; pbk £12.30.*

Machines that Think. ISAAC ASIMOV, PATRICIA S. WARRICK and MARTIN H. GREENBERG (eds). *Allen Lane: 1984. Pp.626. ISBN 0-7139-1685-0. £10.95.*

New for immunology and assay

This week's feature covers new immunological products, reagents, sera, monoclonal antibodies and ELISA kits.

● A highly purified peroxidase especially developed as a marker enzyme for enzyme immunoassays is now available from Boehringer Mannheim. The salt-free lyophilizate has a specific activity of at least 250 U per mg (25°C) and a purity number higher than 3.0. The preparation may be used directly for the conjugation without pretreatment.
Circle No. 100 on Reader Service Card.

● The Biomedical Technologies, Inc. epidermal growth factor (EGF) radioreceptor assay kit is capable of measuring the levels of EGF, and also measures other EGF-like peptides from a variety of biological fluids. The term EGF-like peptides includes the peptides termed collectively transforming growth factor-α (TGF-α). The TGF-alpha proteins, including some proteins produced by transformed cell lines, compete equally for the EGF receptor. The assay measures EGF/TGF-α from a variety of species including mouse and human. Assay sensitivity. is 20 picograms per tube.
Circle No. 101 on Reader Service Card.

● Sanbio b.v. of the Netherlands has introduced a large range of monoclonal antibodies for indirect immunoperoxidase staining on tissues and enzyme-linked immunosorbent assay (ELISA) techniques. The series includes anti-human keratin, neurofilament, human chorionic gonadotropin, follicle stimulating hormone and glia fibrillary acidic protein, anti-human vimentin, thyroglobulin and blood vessel endothelium. Sanbio also produces a range of monoclonal antibodies: anti-human T cells and an anti-rat tubulin which will stain eukaryotic cells grown in cell culture as well as frozen sections of tissues. In the United States, Sanbio products are distributed by Accurate Chemical and Scientific Corporation.
Circle No. 102 on Reader Service Card.

● Tissue polypeptide antigen (TPA) is a protein associated with cytoskeletal intermediate filaments of internal epithelial (and hence carcinoma) cells. Rabbit anti-TPA antibody, supplied as 10ml of prediluted liquid, can be used for the specific staining of tumour cells in tissue sections using immuno-enzyme techniques. Monitoring serum TPA released by developing tumours using the Prolifigen RIA kit from Sangtec Medical is of use in the control of treatment and detection of recurrence in several types of cancer including breast and intestinal carcinomas. The kit is sufficient for 100 assay tubes. Products are available through Sangtec Medical in Stockholm and through distributors.
Circle No. 103 on Reader Service Card.

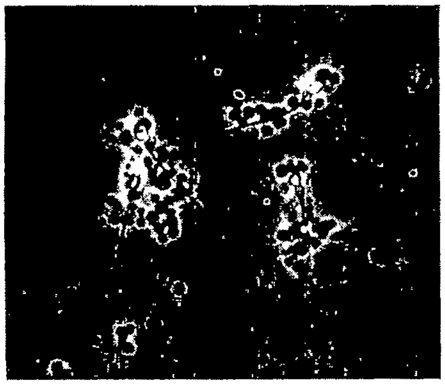
● What is claimed to be the first commercially available monoclonal antibody against choline acetyltransferase has been launched by Boehringer Mannheim. This antibody should be of considerable value in the study of the role of cholinergic neurones in the function of the central nervous system. The neurotransmitter synthesizing enzyme choline acetyltransferase is the only reliable marker for cholinergic cells. Immunological demonstration of this enzyme was possible only when highly purified choline acetyltransferase was available as an antigen in order to produce this monoclonal antibody.
Circle No. 104 on Reader Service Card.

● The factor VIII related antigen immunoperoxidase staining kit produced by Biomeda uses avidin–biotin immunotechnology. This immunohistochemical kit is designed to recognize the presence of this blood vessel-endothelial cell marker in paraffin-embedded and frozen tissue sections. The Histoscan-FX VIII kit yields a highly contrasting red colour in positively stained sections. The morphological characteristic of the tissue under study is revealed by the haematoxylin stain which is also part of the kit. The staining methodology using the avidin–biotin affinity cytochemistry (ABAC) gives outstanding staining of tissue sections, and allows very short but efficient incubation steps. The kit is available in two size configurations containing all basic reagents needed to stain either 50 or 150 tissue sections up to the mounting stage. The reagents forming these kits are supplied in a ready-to-use form and are contained in convenient dropper bottles which, for simplicity of use, are both colour and numerically coded.
Circle No. 105 on Reader Service Card.

● A new modular system has been introduced by A/S Nunc of Denmark for ELISA and other analyses. The MicroWell Module consists of a frame, into which different types of modules can be fixed to meet individual requirements. The module system is composed of 1 × 8 and 2 × 8 well modules with flat bottoms and 2 × 8 well modules with round bottoms. All three versions are available with high and with medium binding capacity. The frames and the wells of the modules have the same dimensions as a traditional 96-well plate and can thus be used in existing readers, dispensers, washers and so on. The well bottoms are protected against scratches, and selfstanding modules. The same frame is applicable for all the different types of modules. MicroWell Modules are supplied either as loose modules, empty frames or as modules mounted in frames.
Circle No. 106 on Reader Service Card.

● Antisera to human thyroglobulin and thyroid binding globulin (TBG) are the latest additions to Miles Scientific's line of undiluted hormone/protein antisera. These products are useful in a variety of procedures including gel diffusion, immunohistology and RIA. Anti-human thyroglobulin is a whole serum product enriched by the addition of a concentrated IgG fraction of the same antiserum. The antiserum is produced in sheep, using an antigen prepared from thyroid. Using the peroxidase–anti-peroxidase (PAP) technique, this antiserum has titres of approximately 1:100 against normal thyroid and 1:500 against secondary tumours following thyroidectomy. Anti-human thyroid binding globulin is also an IgG fraction-enriched antiserum. The antigen used is purified from human plasma.
Circle No. 107 on Reader Service Card.

One of the range of ELISA-based kits from Labsystems, this one designed for the diagnosis of cytomegalovirus infection. Circle number 110 for details.



Detection of anti-sperm antibodies with Immunobead from Bio-Rad.

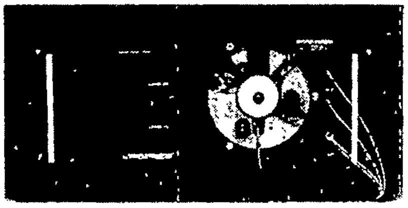
- A rosette-type assay using Bio-Rad's Immunobead reagent allows rapid and reliable detection of anti-sperm antibodies. The assay, performed in 30 minutes, requires only basic laboratory equipment and commercially available reagents. The test can be used either for detection of autoantibodies which are already bound to sperm in semen, or for detection of free anti-sperm antibodies in fluids such as seminal plasma, serum, follicular fluid, or cervical mucus.

Circle No. 108 on Reader Service Card.

- The Hamilton Microlab M liquid handling system features versatile program storage in a battery buffered memory, making it especially suitable for RIA work. Microlab 1000 is a dual syringe unit, ideal when high dilution ratios are required, and capable of repeat dispense and double dilutions. The most recent addition to the Hamilton range is the Microlab MT, for use with microtitre plates.

Circle No. 109 on Reader Service Card.

ADVERTISEMENTS



Liposomes

LIPOPREP® the equipment for the reproducible preparation of stable unilamellar liposomes of defined size in the range of 30-300 nm Ø with extremely narrow particle size distribution for e.g. the efficient incorporation of (therapeutic) agents incl antibodies.

DIANORM-Geräte, P.O. Box 126, D-8 München 65, FRG

Circle No.51 on Reader Service Card.

- Five test kits, based on the ELISA technique, are available from Labsystems (UK) Limited. Tetanus IgG EIA kits provide for practical and convenient screening of tetanus antitoxin. The normal sensitivity is 0.1 mIU ml^{-1} but, if necessary, a more rapid less sensitive test may be performed by decreasing the incubation time to one hour. The CMV IgG EIA test kit allows accurate diagnosis of cytomegalovirus infections. The assay speeds up CMV antibody testing considerably, especially in large screening tests. A positive IgG test suggests previous infection. All the kits are based on solid phase enzyme immunoassay, automatic photometric reading and simple laboratory work. Each kit is complete with all the necessary reagents, sensitized Microstrips or cuvette blocks for the tests.

Circle No. 110 on Reader Service Card.

- A new cell marker, DiI-Ac-LDL (1,1′-dioctadecyl-1-3, 3′, 3′-tetramethyl-indocarbocyanine perchlorate acetylated low density lipoprotein) labels both vascular endothelial cells and macrophages. It can be used to identify and/or isolate these cells from mixed cell populations. When cells are labelled with DiI-Ac-LDL, the lipoprotein is degraded by lysosomal enzymes and the DiI (fluorescent probe) accumulates in the intracellular membranes; there is no effect on cell viability. DiI-Ac-LDL is available from Biomedical Technologies Inc. of Cambridge, Massachusetts.

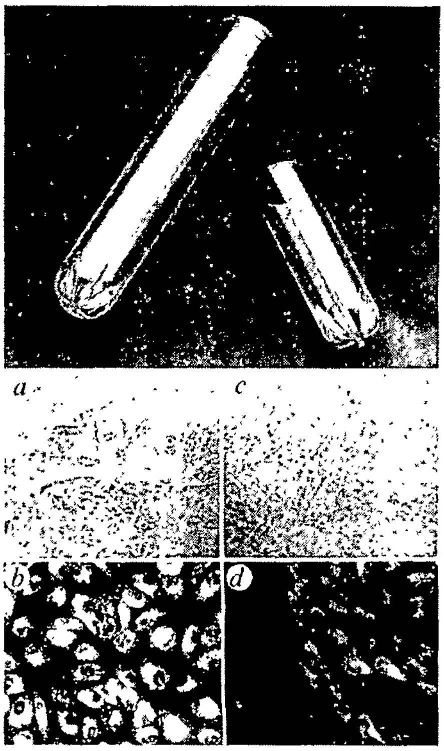
Circle No. 111 on Reader Service Card.

- Leukotriene B_4 can now be measured accurately and conveniently in biological samples using a radioimmunoassay reagents system from Amersham International. The new product consists of ^{3}H-leukotriene B_4 tracer, high specificity antiserum and leukotriene B_4 standard. The measurement range is 12.5 to 400 pg per tube and sufficient reagents are supplied for 125 assay tubes. This permits the construction of a standard curve and the measurement of 53 unknowns in duplicate, but as unused reagents can be stored, a standard curve may be constructed on more than one occasion.

Circle No. 112 on Reader Service Card.

- The ImmunoReader NJ-2000 from Tissue Culture Services is a new approach to automated quantitative photometry. All operations are controlled by an advanced microprocessor which makes it possible to combine a number of standard modes with various parameters as requested by the user. As the NJ-2000 can read up to 15 microplates in sequence, it is suitable for clinical applications and permits a high volume of tests to be performed. Using a keyboard combined with digital displays, the NJ-2000 can be operated without specialized training and user-specific programs can be designed to suit individual analytical needs. Once created, the built-in memory in the NJ-2000 allows eleven programs to be stored for later retrieval when needed.

Circle No. 113 on Reader Service Card.



Top: Nunc's StarTube for ELISA and RIA. Bottom: Micrographs of cells labelled with the new cell marker from Biomedical Technologies. a, *Phase and* b, *fluorescence migrographs of a pure culture of bovine aortic endothelial cells.* c, *Phase and* d, *fluorescence micrographs of bovine aortic smooth muscle cells and endothelial cells.*

- The Nunc StarTube is a specialist tube for ELISA and RIA analyses. It is a round-bottomed polystyrene tube with six wings — a star — on the inside of the tube bottom. The purpose of the star is to increase the surface and thereby make it possible to adsorb greater amounts, more rapidly than is the case with traditional tubes. We have succeeded in increasing the surface by 50–100% dependent on the amount of liquid. The StarTube is manufactured from the same type of polystyrene as the Nunc-Immuno Plate I, and it can thus adsorb 400 ng immunoglobulins per cm^2 compared with a tube manufactured from ordinary polystyrene, which will only adsorb 100 ng per cm^2. The special design of the tube bottom makes it possible to reduce the time required for coating and incubation by about two-thirds without influencing the sensitivity of the analysis. The StarTube is available in two versions: 40 × 10.5 mm and 75 × 12 mm.

Circle No. 114 on Reader Service Card.

- Cellular Products, Inc. of Buffalo, New York and Cordis Laboratories, Inc., of Miami, Florida, have entered into an agreement to jointly produce and market test kits for the detection of antibodies to human T-lymphotrophic viruses (HTLV). Kits are available for both HTLV-I and the AIDS virus (HTLV-III). The system provides quantitative results in less than 3 hours at an approximate cost of $2.00 per determination.

Circle No. 115 on Reader Service Card.

- A new method for measuring levels of the immunosuppressant cyclosporin has been developed by Water Associates. The HPLC assay monitors cyclosporin in patients without cross-reactivity with its metabolites. Unlike RIA kits, the 15-min assay separates cyclosporin from its metabolites to allow better patient management. Samples are prepared in 30 min using a simple extraction procedure.
Circle No. 116 on Reader Service Card.

- The new electron microscopy grade colloidal gold probes from Janssen are virtually cluster-free immunogold particles with a narrow size distribution. EM-grade colloidal gold is available in four non-overlapping sizes, coupled to secondary antibodies of various specificities, or protein A. Light microscopy (LM) grade immunogold can be used in conjunction with epi-polarization (anti-mouse secondary antibody only) or with the ImmunoGold silver staining technique. An immunoblotting (BL) grade range has been developed for the immunochemical visualization of antigen-antibody reactions at the surface of blotting membranes.
Circle No. 117 on Reader Service Card.

- For use with glucose oxidase in immunohistochemical staining processes, Vector Labs has introduced several glucose oxidase substrate kits as companion reagents to Vecta stain ABC-GO immunohistochemical staining kits. Each substrate kit contains optimal concentrations of reagents in convenient dropper bottles and includes a mixing bottle for preparing the substrate solution. The colour of the reaction product depends on the tetrazolium salt supplied with the kit. Three kits are available with a choice of reaction product colours — black, red or purple-blue. The substrate kits include easy to follow instructions and sufficient stock solutions to prepare approximately 300 ml of substrate solution.
Circle No. 118 on Reader Service Card.

- Affinity purified anti-pig IgG (γ) and IgM (μ) are available from Kirkegaard and Perry of Gaithersburg, Maryland. These heavy chain specific polyclonal antibodies were isolated from goat antisera immunized with normal pig IgG or IgM and then affinity purified by exhaustive adsorption on pig IgM and IgG respectively to insure minimal cross-reactivity and high purity. Both antibodies are especially suited to high performance immunoassays that differentiate current and past infections by distinguishing pig IgG or IgM activity. These antibodies are available unlabelled and as peroxidase, phosphatase or fluorescein conjugates.
Circle No. 119 on Reader Service Card.

- Nycodenz Monocytes is a new medium from Nyegaard designed for the one-step isolation of monocytes from leukocyte rich plasma and whole blood. The method is claimed to yield monocytes of high purity (over 90%), good yield (over 60%) and good viability.
Circle No. 120 on Reader Service Card.

- The new 120-page catalogue from Miles Scientific includes an extensive range of immunochemicals. The other products listed are divided into separate sections including: Lectins, Blood Proteins, Polypeptides, Enzymes and Companion Reagents. The catalogue also includes description of LUX tissue culture labware and Lab-Tek general labware.
Circle No. 121 on Reader Service Card.

- The Tago range of antisera now includes goat antisera to human proteins; fluorescein conjugated IgG fractions; antibodies to mouse immunoglobulins; goat anti-rat IgG and goat F(ab′)2 fractions from pepsin-digested affinity isolated antibodies. Both affinity adsorption and affinity isolation are used to purify the Tago reagents.
Circle No. 122 on Reader Service Card.

- A wide range of Bio-Yeda biological products, including many immunochemicals, is now available in the United Kingdom through P & S Biochemicals of Liverpool. Bio-Yeda is a subsidiary of Yeda Research and Development Company of the Weizman Institute of Science in Israel. Amongst the variety of immunochemicals available are: monoclonal antibodies to human immunoglobulins, lactate dehydrogenase isozymes and T and B lymphocytes; monoclonals to DNP, mouse lymphocyte markers and many hormones and drugs; fluorescent and alkaline phosphatase conjugated monoclonals, and monoclonal peroxidase anti-peroxidase complexes. Antisera to almost 100 different human, animal and general cytoskeletal proteins are available. Other Bio-Yeda immunochemicals available include RID plates, IgG fractions of antisera, affinity purified antibodies , RIA/EIA reagents (plus RIA second antibodies) and protein A reagents.
Circle No. 123 on Reader Service Card.

- T-cell growth factor (TCGF, interleukin 2) has been added to Metachem's range of growth and attachment factors. The TCGF is from human leukocytes and is available in 5 ml quantities in sterile, lectin-free liquid containing a small amount of calf serum. The growth factor is stable for one year when stored at 4°C or for 3 days at room temperature.
Circle No. 124 on Reader Service Card.

- The new Imagen RSV test from Boots-Celltech Diagnostics provides an accurate diagnosis of respiratory synctial virus infection within 30 min. The Imagen RSV test is a rapid, simple direct immunofluorescence test utilizing monoclonal antibodies specific to RSV. This is the second product in the Imagen range to be made available, the first being the Imagen Chlamydia test which was launched earlier this year.
Circle No. 125 on Reader Service Card.

These notes are based on information provided by the manufacturers. For further details circle the appropriate numbers on the Reader Service Card bound inside the journal.

- Hybridoma reagents designed for the easy purification of monoclonal antibodies, titred interleukin 2 (in three purity levels), T-cell reagents and protein-A reagents are now available from Inter-Cell Technologies, Inc. of Somerville, New Jersey. Also available from Inter-Cell are antisera and IgG fractions to human and animal proteins and cells, a wide range of complement reagents, adsorbed antisera with improved specificity to individual cell populations and lymphocytes useful as starting matrials for lymphokine production or the isolation of lymphocyte subsets. In addition, Inter-Cell includes among its services custom immunological assays and antisera production.
Circle No. 126 on Reader Service Card.

- A new reagent for immunological research *in vitro* and in laboratory animals removes viability, infectivity and oncogenicity of the viruses (through photochemical inactivation of nucleic acid functions) to provide a new degree of experimental freedom. The reagents, from Lee Biomolecular, are provided in sterile lyophilized form having good shelf life, eliminating the need to propagate, inactivate and standardize viruses in the user's laboratory. More than seventy human and veterinary viruses are listed in the catalogue including herpes simplex, cytomegalovirus, Epstein–Barr and simian virus 40.

A. Gatto,

ANNOUNCEMENTS

Meetings

17-18 December, **Meeting on Metal Ions, Free Radical Reactions and Disease,** London (Mr B. Halliwell, Department of Biochemistry, King's College, Strand, London WC2R 2LS, UK).

25 February-1 March, **36th Pittsburg Conference and Exposition on Analytical Chemistry and Applied Spectroscopy,** New Orleans, USA (Mrs Linda Briggs, Program Secretary, 437 Donald Road, Pittsburgh, Pennsylvania, 15235, USA).

26 February-8 March, **Winter Session on Disordered Systems and Biological Organization,** Les Houches, France (Mr G. Weisbuch, Centre de Physique, Univ. Scientifique et Medicale de Grenoble, Côte des Chavants, 74310 Les Houches France).

26-29 March, **3rd European Conference on Food Chemistry,** Antwerp, Belgium (Euro Food Chem. III, Flemish Chemical Society — Food Science Section, Dr P. Dirinck, Faculty of Agricultural Sciences, State University of Gent, Coupure Links 653, B-9000 Gent, Belgium).

27-29 March, **Symposium on the Oceanography of the Rockall Channel** organized by the Royal Society of Edinburgh and the Scottish Marine Biological Association, Edinburgh, UK (The Meeting's Secretary, The Royal Society of Edinburgh, 22,24 George Street, Edinburgh EH2 2PQ, UK).

31 March-4 April, **Meeting on Process Systems Engineering:** SPE '85 — The Use of Computers in Chemical Engineering, Cambridge, UK. The Institution of Chemical Engineers, 165-171 Railway Terrace, Rugby CV21 3HQ, UK).

31 March-5 April, **4th Pfefferkorn Conference on The Science of Biological Specimen Preparation for Microscopy and Microanalysis,** Las Vegas, USA (Dr. Om Johari, PO Box 66507, AMF O'Hare, Illinois 60666 USA).

10-12 April, Symposium on **Recent Advances in Medical and Physiological Imagery,** Harrow Middlesex, UK (Mr M. Goff, Thermographic Laboratory, Clinical Rsearch Centre, Watford Road, Harrow, Middlesex HA1 3UJ, UK).

15-19 April, **International Symposium on Biomineralization in Lower Plants and Animals,** Birmingham, UK (Dr Robert Riding, Biomineralization Symposium, Department of Geology, University College, Cardiff CF1 1XL, UK).

16-18 April, **International Meeting on Pregnancy Proteins in Animals,** Copenhagen, Denmark (Ms Ulla Salado-Jimena, Department of Pathology, Laboratory Animal Unit, Royal Veterinary and Agricultural University of Copenhagen, Bülowsvej 13, Dk-1870 Copenhagen V, Denmark).

22-26 April, **International Symposium-Workshop on Particulate and Multi-Phase Processes, & 16th Annual Meeting of the Fine Particle Society,** Miami Beach, USA (Mr T. Nejat Veziroglu, Director, Clean Energy Research Institute, University of Miami, PO Box 248294, Florida 33124, USA).

24-26 April, **International Symposium on Peptides and Ion Transport,** Florence, Italy (Organizing Secretary, Fondazione Giovanni Lorenzi, Via Monte Napoleone 23, 20121 Milan, Italy).

9-15 June, **21st Chemical Engineering Exhibition,** Frankfurt, FRG (Ms A. Bondaray, V.I.P. Business & Trade Fairs Travel Ltd, 42 North Audley Street, Grosvenor Square, London W1A 4PY, UK).

18-20 June, **Conference on Forest Decline,** Goslar, FRG (Verein Deutscher Ingenieure, Kommission Reinhaltan der Luft, POB 1139 D-4000 Düsseldorf 1, FRG).

The Institute of Physics, London, is holding a series of one-day meetings in London this autumn: 17 October, **Electronics Update;** 23 October, **Applications of Non-linear Analysis,** and **Resonator Sensor Systems;** 24 October, **Critical Phenomena in Magnetism and Low Temperature Physics;** 29 October, **Fundamental Aspects of Polymer Flammability;** 6 November, **Magnetic Thin Film Coatings for the Recording Media;** 8 November, **Low Temperature Techniques Course;** 14 November, **High Complexity Displays;** 21 November, **Drying and Curing;** 5 December, **Electrostatic Imaging;** 12 December, **Transient Annealing of Semiconductors;** 14 December, **Permanent Magnetic Materials and Applications.** Further information from The Meetings Office, The Institute of Physics, 47 Belgrave Square, London SW1X 8QX, UK.

The Scientists Center for Animal Welfare USA, are sponsoring three workshops on **Animals and the Scientist : Institutional Responsibilities,** and **"How to Run an Effective Animal Care and Use Committee,** in conjunction with the following universities: 11-12 October, Michigan State University, Lansing Michigan; 14-15 November, University of Southern California, Los Angeles; and 23-24 May 1985, Aspen Institute, Aspen, Colorado (Dr Barbara Orlans, Scientists Center for Animal Welfare, PO Box 9581, Washington D.C. 20016, USA).

Short courses

19-22 November, **Training Course in Fluid Rheology** (Mr L.J. Viney, Warren Spring Laboratory, Gunnels Wood Road, Stevenage, Hertfordshire SG1 2BX, UK).

10-12 December, **Yield of Cereals** (Warwick University, UK); 12-14 December, **Yield of Potatoes** (Warwick University, UK) and 5-7 February, **Yield of Sugar Beet** (Peterborough, UK). Further details form the Arable Unit, National Agricultural Centre, Stoneleigh, Kenilworth, Warwickshire CV8 2LZ, UK).

23 April-29 June 1985, **Understanding Climate** (Dr T.M.L. Wigley, Director, Climatic Research Unit, University of East Anglia, Norwich NR4 7TJ, UK).

6-25 January, **International Training Courses on Gene Transfer in Higher Eukaryotes,** Sofia, Bulgaria (Professor R.G. Tsanev, Institute of Molecular Biology, Bulgarian Academy of Sciences, 1113 Sofia, Bulgaria).

3-7 June 1985, **Second International Summer School on Mathematica Modelling in Physiology and Clinical Medicine,** University of Padua, Italy (E.R. Carson, Research Centre f Measurement and Information i Medicine, The City University, Northampton Square, London EC1, UK.

The Centre for Extension Studies, Loughborough University is organizing a programme of five modular short courses in 1985, leading to the University Diploma in Occupational Health and Safety Management (Mrs K. Gilbert, Centre for Extension Studies, Loughborough University of Technology, Loughborough, Leicestershire LE11 3TU, UK).

Miscellaneous

The Royal College of Pathologists is introducing a Final Examination in Clinical Cytogenetics open to medical and non-medical candidates. Further details are available form the Examinations Department of the Royal College of Pathologists, 2, Carlton House Terrace, London SW1Y 5AF, UK.

The International Commission on Zoological Nomenclature is calling for nominations for new members to replace staff who are retiring. Nominations should be sent by the end of December 1984 to The Secretary, International Commission on Zoological Nomenclature, British Museum (Natural History), Cromwell Road, London SW7 5BD, UK.

It was recently announced that the **British Computer Society** had been granted a Royal Charter by Her Majesty the Queen.

The **Nobeyama Radio Observatory (NRO)** has decided to make its 45m telescope available to foreign scientists from January — May 1985 and is calling for study proposals for its use. Those scientists having a Japanese co-investigator will be preferred although in a limited number of cases applications from those without Japanese co-investigators will also be accepted. The deadline for applications will be at the end of October 1984 and further details can be obtained from K. Akabane, Director, Nobeyama Radio Observatory, Nobeyama, Minamisaku, Nagano 384-13, Japan.

A **Trauma Research Center,** one of the largest of its kind in the world, has been established at the Hebrew University-Hadassah Medical School, Israel.

The **European Powder Metallurgy Federation** was formed earlier this year in Clermont Ferrand, Switzerland; further information from Mr Robert Wood, The Metals Society, 1 Carlton House Terrace, London SW1Y 5DB, UK.

Laboratory 85 will now form part of British Laboratory week to be held next year from 17-19 September at Olympia, London, UK.

Nature Indexes

AUTHOR indexes covering each successive volume of *Nature* appear once every two months and are printed as part of the journal. Author indexes have appeared in the following issues: 19 April (Vol. 307); 7 June (Vol. 308); 26 July (Vol. 309). At the end of the year, *Nature* publishes an annual author/subject index distributed separately from weekly issues of the journal. The next subject index will appear early in January 1985.

TWO NEW reliable, up-to-date and complete biotechnology information resources.

Essential aids for everyone concerned with both the old and new biotechnologies — will save you valuable time and money.

EXAMINE ON FREE APPROVAL WITHOUT COMMITMENT

Detailed information on every aspect of biotechnology worldwide

An indispensable guide to:

- ★ Products, services and research worldwide.
- ★ Companies worldwide.
- ★ Government and international agencies worldwide.
- ★ Information sources worldwide.

This **new** world directory, compiled by the eminent biotechnologist Dr. Jim Coombs, provides a mass of authoritative information about **the entire biotechnology industry worldwide.**

Unlike other directories, THE INTERNATIONAL BIOTECHNOLOGY DIRECTORY 1984 —

- is thoroughly international
- features a unique BUYER'S GUIDE to products, research and services
- covers both the old and new biotechnologies

4638

The Directory tells you:

- ★ Who your competition is, and what they are doing.
- ★ Who are potential customers and suppliers.
- ★ Where to buy equipment, chemicals and services.
- ★ Where culture collections are located and what cultures they hold.
- ★ Where to get plants built.
- ★ Who imports/exports biotechnology products in over 20 countries.
- ★ What consultancy services are available.
- ★ Which government departments are associated with biotechnology, and their programmes.

Authoritative author

Dr. Jim Coombs is a Member of the Organising Committee of Biotech 83 and of Bio-Energy 1984, and Scientific Secretary of the Third European Community Energy from Biomass Conference 1984. He is editor of *Biomass* and Joint Secretary of the BABA.

The Directory is designed for use across the whole biotechnology industry by scientists and researchers, sales managers, buyers and consultants. Here you will find: over 2,000 organisations — companies, universities and research centres — listed by country. Government agencies and programmes — listed by country. Societies and associations — listed by country. Databases, journals and newsletters — listed alphabetically. Products listed under more than 1,000 headings.

All compiled by Dr. Coombs from a vast array of sources then meticulously cross-checked to ensure the reliability of the data. Now available to you on FREE APPROVAL.

Evaluates and assesses the whole range of information sources available.

- ★ covers both old and new technologies.
- ★ covers technical and commercial literature.
- ★ covers difficult and hard to trace sources.
- ★ includes over 20 at-a-glance evaluation tables.
- ★ provides an Index of publishers and their addresses.

Dr. Crafts-Lighty, Head of Information and Library Services at Celltech Limited, systematically and critically reviews all the important information sources:

• books • conferences • trade periodicals • research periodicals • computer databases • patents • market surveys • directories • organisations • secondary sources

'Information Sources in Biotechnology' is an invaluable guide to current technical, business and commercial biotechnology information sources for Researchers, Librarians, Information Officers, Businessmen, Investment Analysts, Investors, and Academic Researchers.

Send no money now.
Examine on FREE APPROVAL.

You can take both these new books for 30 days examination without commitment. Decide to keep either or both, then simply pay the accompanying invoice. If you are not completely satisfied, just return the book(s) in good condition within 30 days and that will be the end of the matter. Ensure prompt delivery by completing and returning the order form **now.**
